Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

type PyThreadState

*Part of the [Limited API](#) (as an opaque struct).*

This data structure represents the state of a single thread. The only public data member is:

[PyInterpreterState](#) \*interp

This thread's interpreter state.

void PyEval\_InitThreads()

*Part of the [Stable ABI](#).*

Deprecated function which does nothing.

In Python 3.6 and older, this function created the GIL if it didn't exist.

*Changed in version 3.9:* The function now does nothing.

*Changed in version 3.7:* This function is now called by [Py\\_Initialize\(\)](#), so you don't have to call it yourself anymore.

*Changed in version 3.2:* This function cannot be called before [Py\\_Initialize\(\)](#) anymore.

*Deprecated since version 3.9.*

int PyEval\_ThreadsInitialized()

*Part of the [Stable ABI](#).*

Returns a non-zero value if [PyEval\\_InitThreads\(\)](#) has been called. This function can be called without holding the GIL, and therefore can be used to avoid calls to the locking

API when running single-threaded.

*Changed in version 3.7:* The [GIL](#) is now initialized by [Py\\_Initialize\(\)](#).

*Deprecated since version 3.9.*

[PyThreadState](#) \*PyEval\_SaveThread()

*Part of the [Stable ABI](#).*

Release the global interpreter lock (if it has been created) and reset the thread state to `NULL`, returning the previous thread state (which is not `NULL`). If the lock has been created, the current thread must have acquired it.

`void PyEval_RestoreThread(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Acquire the global interpreter lock (if it has been created) and set the thread state to *tstate*, which must not be `NULL`. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues.

### Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use [\\_Py\\_IsFinalizing\(\)](#) or [sys.is\\_finalizing\(\)](#) to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

[PyThreadState](#) \*PyThreadState\_Get()

*Part of the [Stable ABI](#).*

Return the current thread state. The global interpreter lock must be held. When the current thread state is `NULL`, this issues a fatal error (so that the caller needn't check for `NULL`).

`PyThreadState *PyThreadState_Swap(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Swap the current thread state with the thread state given by the argument *tstate*, which may be `NULL`. The global interpreter lock must be held and is not released.

The following functions use thread-local storage, and are not compatible with sub-interpreters:

`PyGILState_STATE PyGILState_Ensure()`

*Part of the [Stable ABI](#).*

Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of the global interpreter lock. This may be called as many times as desired by a thread as long as each call is matched with a call to `PyGILState_Release()`. In general, other thread-related APIs may be used between `PyGILState_Ensure()` and `PyGILState_Release()` calls as long as the thread state is restored to its previous state before the `Release()`. For example, normal usage of the `Py_BEGIN_ALLOW_THREADS` and `Py_END_ALLOW_THREADS` macros is acceptable.

The return value is an opaque “handle” to the thread state when `PyGILState_Ensure()` was called, and must be passed to `PyGILState_Release()` to ensure Python is left in the same state. Even though recursive calls are allowed, these handles *cannot* be shared - each unique call to `PyGILState_Ensure()` must save the handle for its call to `PyGILState_Release()`.

When the function returns, the current thread will hold the GIL and be able to call arbitrary Python code. Failure is a fatal error.

### Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use `_Py_IsFinalizing()` or `sys.is_finalizing()` to

check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

`void PyGILState_Release(PyGILState_STATE)`

*Part of the [Stable ABI](#).*

Release any resources previously acquired. After this call, Python's state will be the same as it was prior to the corresponding `PyGILState_Ensure()` call (but generally this state will be unknown to the caller, hence the use of the GILState API).

Every call to `PyGILState_Ensure()` must be matched by a call to `PyGILState_Release()` on the same thread.

`PyThreadState *PyGILState_GetThisThreadState()`

*Part of the [Stable ABI](#).*

Get the current thread state for this thread. May return `NULL` if no GILState API has been used on the current thread. Note that the main thread always has such a thread-state, even if no auto-thread-state call has been made on the main thread. This is mainly a helper/diagnostic function.

`int PyGILState_Check()`

Return `1` if the current thread is holding the GIL and `0` otherwise. This function can be called from any thread at any time. Only if it has had its Python thread state initialized and currently is holding the GIL will it return `1`. This is mainly a helper/diagnostic function. It can be useful for example in callback contexts or memory allocation functions when knowing that the GIL is locked can allow the caller to perform sensitive actions or otherwise behave differently.

*New in version 3.4.*

The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

## Py\_BEGIN\_ALLOW\_THREADS

*Part of the [Stable ABI](#).*

This macro expands to `{ PyThreadState *_save; _save = PyEval_SaveThread();`. Note that it contains an opening brace; it must be matched with a following [Py\\_END\\_ALLOW\\_THREADS](#) macro. See above for further discussion of this macro.

## Py\_END\_ALLOW\_THREADS

*Part of the [Stable ABI](#).*

This macro expands to `PyEval_RestoreThread(_save);`. Note that it contains a closing brace; it must be matched with an earlier [Py\\_BEGIN\\_ALLOW\\_THREADS](#) macro. See above for further discussion of this macro.

## Py\_BLOCK\_THREADS

*Part of the [Stable ABI](#).*

This macro expands to `PyEval_RestoreThread(_save);`; it is equivalent to [Py\\_END\\_ALLOW\\_THREADS](#) without the closing brace.

## Py\_UNBLOCK\_THREADS

*Part of the [Stable ABI](#).*

This macro expands to `_save = PyEval_SaveThread();`; it is equivalent to [Py\\_BEGIN\\_ALLOW\\_THREADS](#) without the opening brace and variable declaration.

## Low-level API

All of the following functions must be called after [Py\\_Initialize\(\)](#).

*Changed in version 3.7:* [Py\\_Initialize\(\)](#) now initializes the [GIL](#).

[PyInterpreterState](#) \*PyInterpreterState\_New()

*Part of the [Stable ABI](#).*

Create a new interpreter state object. The global interpreter

lock need not be held, but may be held if it is necessary to serialize calls to this function.

Raises an [auditing event](#)

`cpython.PyInterpreterState_New` with no arguments.

`void PyInterpreterState_Clear(PyInterpreterState *interp)`

*Part of the [Stable ABI](#).*

Reset all information in an interpreter state object. The global interpreter lock must be held.

Raises an [auditing event](#)

`cpython.PyInterpreterState_Clear` with no arguments.

`void PyInterpreterState_Delete(PyInterpreterState *interp)`

*Part of the [Stable ABI](#).*

Destroy an interpreter state object. The global interpreter lock need not be held. The interpreter state must have been reset with a previous call to [PyInterpreterState\\_Clear\(\)](#).

[PyThreadState](#) \*`PyThreadState_New(PyInterpreterState *interp)`

*Part of the [Stable ABI](#).*

Create a new thread state object belonging to the given interpreter object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

`void PyThreadState_Clear(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Reset all information in a thread state object. The global interpreter lock must be held.

*Changed in version 3.9:* This function now calls the **`PyThreadState.on_delete`** callback. Previously, that happened in [PyThreadState\\_Delete\(\)](#).

`void PyThreadState_Delete(PyThreadState *tstate)`

Part of the *Stable ABI*.

Destroy a thread state object. The global interpreter lock need not be held. The thread state must have been reset with a previous call to `PyThreadState_Clear()`.

`void PyThreadState_DeleteCurrent(void)`

Destroy the current thread state and release the global interpreter lock. Like `PyThreadState_Delete()`, the global interpreter lock need not be held. The thread state must have been reset with a previous call to `PyThreadState_Clear()`.

`PyFrameObject *PyThreadState_GetFrame(PyThreadState *tstate)`

Part of the *Stable ABI* since version 3.10.

Get the current frame of the Python thread state *tstate*.

Return a [strong reference](#). Return `NULL` if no frame is currently executing.

See also `PyEval_GetFrame()`.

*tstate* must not be `NULL`.

*New in version 3.9.*

`uint64_t PyThreadState_GetID(PyThreadState *tstate)`

Part of the *Stable ABI* since version 3.10.

Get the unique thread state identifier of the Python thread state *tstate*.

*tstate* must not be `NULL`.

*New in version 3.9.*

`PyInterpreterState *PyThreadState_GetInterpreter(PyThreadState *tstate)`

Part of the *Stable ABI* since version 3.10.

Get the interpreter of the Python thread state *tstate*.

*tstate* must not be `NULL`.

*New in version 3.9.*

`void PyThreadState_EnterTracing(PyThreadState *tstate)`  
Suspend tracing and profiling in the Python thread state *tstate*.

Resume them using the  
`PyThreadState_LeaveTracing()` function.

*New in version 3.11.*

`void PyThreadState_LeaveTracing(PyThreadState *tstate)`  
Resume tracing and profiling in the Python thread state *tstate* suspended by the `PyThreadState_EnterTracing()` function.

See also `PyEval_SetTrace()` and  
`PyEval_SetProfile()` functions.

*New in version 3.11.*

`PyInterpreterState *PyInterpreterState_Get(void)`

*Part of the [Stable ABI](#) since version 3.9.*  
Get the current interpreter.

Issue a fatal error if there no current Python thread state or no current interpreter. It cannot return `NULL`.

The caller must hold the GIL.

*New in version 3.9.*

`int64_t PyInterpreterState_GetID(PyInterpreterState *interp)`

*Part of the [Stable ABI](#) since version 3.7.*  
Return the interpreter's unique ID. If there was any error in doing so then `-1` is returned and an error is set.

The caller must hold the GIL.

*New in version 3.7.*

`PyObject *``PyInterpreterState_GetDict(PyInterpreterState *interp)`

Part of the *Stable ABI* since version 3.8.

Return a dictionary in which interpreter-specific data may be stored. If this function returns `NULL` then no exception has been raised and the caller should assume no interpreter-specific dict is available.

This is not a replacement for `PyModule_GetState()`, which extensions should use to store interpreter-specific state information.

*New in version 3.8.*

`typedef PyObject *(*_PyFrameEvalFunction)(PyThreadState *tstate, _PyInterpreterFrame *frame, int throwflag)`

Type of a frame evaluation function.

The *throwflag* parameter is used by the `throw()` method of generators: if non-zero, handle the current exception.

*Changed in version 3.9:* The function now takes a *tstate* parameter.

*Changed in version 3.11:* The *frame* parameter changed from `PyFrameObject*` to `_PyInterpreterFrame*`.

`_PyFrameEvalFunction`

`_PyInterpreterState_GetEvalFrameFunc(PyInterpreterState *interp)`

Get the frame evaluation function.

See the [PEP 523](https://peps.python.org/pep-0523/) [https://peps.python.org/pep-0523/] “Adding a frame evaluation API to CPython”.

*New in version 3.9.*

`void _PyInterpreterState_SetEvalFrameFunc(PyInterpreterState  
*interp, _PyFrameEvalFunction eval_frame)`

Set the frame evaluation function.

See the [PEP 523](https://peps.python.org/pep-0523/) [https://peps.python.org/pep-0523/] “Adding a frame evaluation API to CPython”.

*New in version 3.9.*

`PyObject *PyThreadState_GetDict()`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns `NULL`, no exception has been raised and the caller should assume no current thread state is available.

`int PyThreadState_SetAsyncExc(unsigned long id, PyObject *exc)`

*Part of the [Stable ABI](#).*

Asynchronously raise an exception in a thread. The *id* argument is the thread id of the target thread; *exc* is the exception object to be raised. This function does not steal any references to *exc*. To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn’t found. If *exc* is `NULL`, the pending exception (if any) for the thread is cleared. This raises no exceptions.

*Changed in version 3.7:* The type of the *id* parameter changed from `long` to `unsigned long`.

`void PyEval_AcquireThread(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Acquire the global interpreter lock and set the current thread state to *tstate*, which must not be `NULL`. The lock must have been created earlier. If this thread already has the lock,

deadlock ensues.

### Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use `_Py_IsFinalizing()` or `sys.is_finalizing()` to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

*Changed in version 3.8:* Updated to be consistent with `PyEval_RestoreThread()`, `Py_END_ALLOW_THREADS()`, and `PyGILState_Ensure()`, and terminate the current thread if called while the interpreter is finalizing.

`PyEval_RestoreThread()` is a higher-level function which is always available (even when threads have not been initialized).

`void PyEval_ReleaseThread(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Reset the current thread state to `NULL` and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The `tstate` argument, which must not be `NULL`, is only used to check that it represents the current thread state — if it isn't, a fatal error is reported.

`PyEval_SaveThread()` is a higher-level function which is always available (even when threads have not been initialized).

`void PyEval_AcquireLock()`

*Part of the [Stable ABI](#).*

Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues.

*Deprecated since version 3.2:* This function does not update the current thread state. Please use `PyEval_RestoreThread()` or `PyEval_AcquireThread()` instead.

## Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use `_Py_IsFinalizing()` or `sys.is_finalizing()` to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

*Changed in version 3.8:* Updated to be consistent with `PyEval_RestoreThread()`, `Py_END_ALLOW_THREADS()`, and `PyGILState_Ensure()`, and terminate the current thread if called while the interpreter is finalizing.

`void PyEval_ReleaseLock()`

*Part of the [Stable ABI](#).*

Release the global interpreter lock. The lock must have been created earlier.

*Deprecated since version 3.2:* This function does not update the current thread state. Please use `PyEval_SaveThread()` or `PyEval_ReleaseThread()` instead.

## Sub-interpreter support

While in most uses, you will only embed a single Python interpreter, there are cases where you need to create several independent interpreters in the same process and perhaps even in the same thread. Sub-interpreters allow you to do that.

The “main” interpreter is the first one created when the runtime initializes. It is usually the only Python interpreter in a process. Unlike sub-interpreters, the main interpreter has unique process-global responsibilities like signal handling. It is also responsible for execution during runtime initialization and is usually the active

interpreter during runtime finalization. The

`PyInterpreterState_Main()` function returns a pointer to its state.

You can switch between sub-interpreters using the

`PyThreadState_Swap()` function. You can create and destroy them using the following functions:

type `PyInterpreterConfig`

Structure containing most parameters to configure a sub-interpreter. Its values are used only in

`Py_NewInterpreterFromConfig()` and never modified by the runtime.

*New in version 3.12.*

Structure fields:

`int use_main_obmalloc`

If this is 0 then the sub-interpreter will use its own “object” allocator state. Otherwise it will use (share) the main interpreter’s.

If this is 0 then

`check_multi_interp_extensions` must be 1 (non-zero). If this is 1 then `gil` must not be `PyInterpreterConfig_OWN_GIL`.

`int allow_fork`

If this is 0 then the runtime will not support forking the process in any thread where the sub-interpreter is currently active. Otherwise fork is unrestricted.

Note that the `subprocess` module still works when fork is disallowed.

`int allow_exec`

If this is 0 then the runtime will not support replacing the current process via `exec` (e.g. `os.execv()`) in any thread where the sub-interpreter is currently active.

Otherwise `exec` is unrestricted.

Note that the `subprocess` module still works when `exec` is disallowed.

`int allow_threads`

If this is `0` then the sub-interpreter's `threading` module won't create threads. Otherwise threads are allowed.

`int allow_daemon_threads`

If this is `0` then the sub-interpreter's `threading` module won't create daemon threads. Otherwise daemon threads are allowed (as long as `allow_threads` is non-zero).

`int check_multi_interp_extensions`

If this is `0` then all extension modules may be imported, including legacy (single-phase init) modules, in any thread where the sub-interpreter is currently active. Otherwise only multi-phase init extension modules (see [PEP 489](https://peps.python.org/pep-0489/) [https://peps.python.org/pep-0489/]) may be imported. (Also see [Py\\_mod\\_multiple\\_interpreters.](#))

This must be `1` (non-zero) if `use_main_obmalloc` is `0`.

`int gil`

This determines the operation of the GIL for the sub-interpreter. It may be one of the following:

`PyInterpreterConfig_DEFAULT_GIL`

Use the default selection  
([PyInterpreterConfig\\_SHARED\\_GIL](#)).

`PyInterpreterConfig_SHARED_GIL`

Use (share) the main interpreter's GIL.

`PyInterpreterConfig_OWN_GIL`

Use the sub-interpreter's own GIL.

If this is `PyInterpreterConfig_OWN_GIL` then `PyInterpreterConfig.use_main_obmalloc` must be 0.

`PyStatus` `Py_NewInterpreterFromConfig(PyThreadState **tstate_p,`  
`const PyInterpreterConfig *config)`

Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules `builtins`, `__main__` and `sys`. The table of loaded modules (`sys.modules`) and the module search path (`sys.path`) are also separate. The new environment has no `sys.argv` variable. It has new standard I/O stream file objects `sys.stdin`, `sys.stdout` and `sys.stderr` (however these refer to the same underlying file descriptors).

The given *config* controls the options with which the interpreter is initialized.

Upon success, *tstate\_p* will be set to the first thread state created in the new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, *tstate\_p* is set to `NULL`; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state.

Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still held when it returns. Likewise a current thread state must be set on entry. On success, the returned thread state will be set as current. If the sub-interpreter is created with its own GIL then the GIL of the calling interpreter will be released. When the function returns, the new interpreter's GIL will be held by the

current thread and the previously interpreter's GIL will remain released here.

*New in version 3.12.*

Sub-interpreters are most effective when isolated from each other, with certain functionality restricted:

```
PyInterpreterConfig config = {
    .use_main_obmalloc = 0,
    .allow_fork = 0,
    .allow_exec = 0,
    .allow_threads = 1,
    .allow_daemon_threads = 0,
    .check_multi_interp_extensions = 1,
    .gil = PyInterpreterConfig_OWN_GIL,
};
PyThreadState *tstate = Py_NewInterpreterFromConfig
```

Note that the config is used only briefly and does not get modified. During initialization the config's values are converted into various `PyInterpreterState` values. A read-only copy of the config may be stored internally on the `PyInterpreterState`.

Extension modules are shared between (sub-)interpreters as follows:

- For modules using multi-phase initialization, e.g. `PyModule_FromDefAndSpec()`, a separate module object is created and initialized for each interpreter. Only C-level static and global variables are shared between these module objects.
- For modules using single-phase initialization, e.g. `PyModule_Create()`, the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's `init`

function is not called. Objects in the module's dictionary thus end up shared across (sub-)interpreters, which might cause unwanted behavior (see [Bugs and caveats](#) below).

Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling `Py_FinalizeEx()` and `Py_Initialize()`; in that case, the extension's `initmodule` function is called again. As with multi-phase initialization, this means that only C-level static and global variables are shared between these modules.

`PyThreadState *Py_NewInterpreter(void)`

*Part of the [Stable ABI](#).*

Create a new sub-interpreter. This is essentially just a wrapper around `Py_NewInterpreterFromConfig()` with a config that preserves the existing behavior. The result is an unisolated sub-interpreter that shares the main interpreter's GIL, allows fork/exec, allows daemon threads, and allows single-phase init modules.

`void Py_EndInterpreter(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is `NULL`. All thread states associated with this interpreter are destroyed. The global interpreter lock used by the target interpreter must be held before calling this function. No GIL is held when it returns.

`Py_FinalizeEx()` will destroy all sub-interpreters that haven't been explicitly destroyed at that point.

## A Per-Interpreter GIL

Using `Py_NewInterpreterFromConfig()` you can create a sub-interpreter that is completely isolated from other interpreters, including having its own GIL. The most important benefit of this isolation is that such an interpreter can execute Python code without being blocked by other interpreters or blocking any others. Thus a single Python process can truly take advantage of multiple CPU cores when running Python code. The isolation also encourages a different approach to concurrency than that of just using threads. (See [PEP 554](https://peps.python.org/pep-0554/) [https://peps.python.org/pep-0554/].)

Using an isolated interpreter requires vigilance in preserving that isolation. That especially means not sharing any objects or mutable state without guarantees about thread-safety. Even objects that are otherwise immutable (e.g. `None`, `(1, 5)`) can't normally be shared because of the refcount. One simple but less-efficient approach around this is to use a global lock around all use of some state (or object). Alternately, effectively immutable objects (like integers or strings) can be made safe in spite of their refcounts by making them “immortal”. In fact, this has been done for the builtin singletons, small integers, and a number of other builtin objects.

If you preserve isolation then you will have access to proper multi-core computing without the complications that come with free-threading. Failure to preserve isolation will expose you to the full consequences of free-threading, including races and hard-to-debug crashes.

Aside from that, one of the main challenges of using multiple isolated interpreters is how to communicate between them safely (not break isolation) and efficiently. The runtime and stdlib do not provide any standard approach to this yet. A future stdlib module would help mitigate the effort of preserving isolation and expose effective tools for communicating (and sharing) data between interpreters.

*New in version 3.12.*

## Bugs and caveats

Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect — for

example, using low-level file operations like `os.close()` they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when using single-phase initialization or (static) global variables. It is possible to insert objects created in one sub-interpreter into a namespace of another (sub-)interpreter; this should be avoided if possible.

Special care should be taken to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter's dictionary of loaded modules. It is equally important to avoid sharing objects from which the above are reachable.

Also note that combining this functionality with `PyGILState_*` APIs is delicate, because these APIs assume a bijection between Python thread states and OS-level threads, an assumption broken by the presence of sub-interpreters. It is highly recommended that you don't switch sub-interpreters between a pair of matching `PyGILState_Ensure()` and `PyGILState_Release()` calls. Furthermore, extensions (such as `ctypes`) using these APIs to allow calling of Python code from non-Python created threads will probably be broken when using sub-interpreters.

## Asynchronous Notifications

A mechanism is provided to make asynchronous notifications to the main interpreter thread. These notifications take the form of a function pointer and a void pointer argument.

```
int Py_AddPendingCall(int (*func)(void*), void *arg)
```

*Part of the [Stable ABI](#).*

Schedule a function to be called from the main interpreter thread. On success, `0` is returned and *func* is queued for being called in the main thread. On failure, `-1` is returned without setting any exception.

When successfully queued, *func* will be *eventually* called from

the main interpreter thread with the argument *arg*. It will be called asynchronously with respect to normally running Python code, but with both these conditions met:

- on a [bytecode](#) boundary;
- with the main thread holding the [global interpreter lock](#) (*func* can therefore use the full C API).

*func* must return 0 on success, or -1 on failure with an exception set. *func* won't be interrupted to perform another asynchronous notification recursively, but it can still be interrupted to switch threads if the global interpreter lock is released.

This function doesn't need a current thread state to run, and it doesn't need the global interpreter lock.

To call this function in a subinterpreter, the caller must hold the GIL. Otherwise, the function *func* can be scheduled to be called from the wrong interpreter.

### Warning

This is a low-level function, only useful for very special cases. There is no guarantee that *func* will be called as quick as possible. If the main thread is busy executing a system call, *func* won't be called before the system call returns. This function is generally **not** suitable for calling Python code from arbitrary C threads. Instead, use the [PyGILState API](#).

*Changed in version 3.9:* If this function is called in a subinterpreter, the function *func* is now scheduled to be called from the subinterpreter, rather than being called from the main interpreter. Each subinterpreter now has its own list of scheduled calls.

*New in version 3.1.*

## Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

```
typedef int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame,
int what, PyObject *arg)
```

The type of the trace function registered using `PyEval_SetProfile()` and `PyEval_SetTrace()`. The first parameter is the object passed to the registration function as *obj*, *frame* is the frame object to which the event pertains, *what* is one of the constants `PyTrace_CALL`, `PyTrace_EXCEPTION`, `PyTrace_LINE`, `PyTrace_RETURN`, `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION`, `PyTrace_C_RETURN`, or `PyTrace_OPCODE`, and *arg* depends on the value of *what*:

### **Meaning of *what***

---

`PyTrace_CALL`. Always

---

`PyTrace_EXCEPTION`. Exception information as returned by `sys.exc_info()`.

---

`PyTrace_LINE`. Always

---

`PyTrace_RETURN`. Value being returned to the caller, or NULL if caused by an exception.

---

`PyTrace_C_CALL`. Function object being called.

---

`PyTrace_C_EXCEPTION`. Function object being called.

---

`PyTrace_C_RETURN`. Function object being called.

---

`PyTrace_OPCODE`. Always

---

`int PyTrace_CALL`

The value of the *what* parameter to a `Py_tracefunc` function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not

reported as there is no control transfer to the Python bytecode in the corresponding frame.

`int PyTrace_EXCEPTION`

The value of the *what* parameter to a `Py_tracefunc` function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

`int PyTrace_LINE`

The value passed as the *what* parameter to a `Py_tracefunc` function (but not a profiling function) when a line-number event is being reported. It may be disabled for a frame by setting `f_trace_lines` to 0 on that frame.

`int PyTrace_RETURN`

The value for the *what* parameter to `Py_tracefunc` functions when a call is about to return.

`int PyTrace_C_CALL`

The value for the *what* parameter to `Py_tracefunc` functions when a C function is about to be called.

`int PyTrace_C_EXCEPTION`

The value for the *what* parameter to `Py_tracefunc` functions when a C function has raised an exception.

`int PyTrace_C_RETURN`

The value for the *what* parameter to `Py_tracefunc` functions when a C function has returned.

`int PyTrace_OPCODE`

The value for the *what* parameter to `Py_tracefunc` functions (but not profiling functions) when a new opcode is about to be executed. This event is not emitted by default: it must be explicitly requested by setting `f_trace_opcodes` to 1 on the frame.

`void PyEval_SetProfile(Py_tracefunc func, PyObject *obj)`

Set the profiler function to *func*. The *obj* parameter is passed to the function as its first parameter, and may be any Python object, or `NULL`. If the profile function needs to maintain state, using a different value for *obj* for each thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except `PyTrace_LINE`, `PyTrace_OPCODE` and `PyTrace_EXCEPTION`.

See also the `sys.setprofile()` function.

The caller must hold the `GIL`.

`void PyEval_SetProfileAllThreads(Py_tracefunc func, PyObject *obj)`

Like `PyEval_SetProfile()` but sets the profile function in all running threads belonging to the current interpreter instead of the setting it only on the current thread.

The caller must hold the `GIL`.

As `PyEval_SetProfile()`, this function ignores any exceptions raised while setting the profile functions in all threads.

*New in version 3.12.*

`void PyEval_SetTrace(Py_tracefunc func, PyObject *obj)`

Set the tracing function to *func*. This is similar to `PyEval_SetProfile()`, except the tracing function does receive line-number events and per-opcode events, but does not receive any event related to C function objects being called. Any trace function registered using

`PyEval_SetTrace()` will not receive `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION` or `PyTrace_C_RETURN` as a value for the *what* parameter.

See also the `sys.settrace()` function.

The caller must hold the GIL.

`void PyEval_SetTraceAllThreads(Py_tracefunc func, PyObject *obj)`

Like `PyEval_SetTrace()` but sets the tracing function in all running threads belonging to the current interpreter instead of the setting it only on the current thread.

The caller must hold the GIL.

As `PyEval_SetTrace()`, this function ignores any exceptions raised while setting the trace functions in all threads.

*New in version 3.12.*

## Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

`PyInterpreterState *PyInterpreterState_Head()`

Return the interpreter state object at the head of the list of all such objects.

`PyInterpreterState *PyInterpreterState_Main()`

Return the main interpreter state object.

`PyInterpreterState *PyInterpreterState_Next(PyInterpreterState *interp)`

Return the next interpreter state object after *interp* from the list of all such objects.

`PyThreadState *PyInterpreterState_ThreadHead(PyInterpreterState *interp)`

Return the pointer to the first `PyThreadState` object in the list of threads associated with the interpreter *interp*.

`PyThreadState *PyThreadState_Next(PyThreadState *tstate)`

Return the next thread state object after *tstate* from the list of all such objects belonging to the same `PyInterpreterState` object.

## Thread Local Storage Support

The Python interpreter provides low-level support for thread-local storage (TLS) which wraps the underlying native TLS implementation to support the Python-level thread local storage API (`threading.local`). The CPython C level APIs are similar to those offered by pthreads and Windows: use a thread key and functions to associate a void\* value per thread.

The GIL does *not* need to be held when calling these functions; they supply their own locking.

Note that `Python.h` does not include the declaration of the TLS APIs, you need to include `pythread.h` to use thread-local storage.

### Note

None of these API functions handle memory management on behalf of the void\* values. You need to allocate and deallocate them yourself. If the void\* values happen to be `PyObject*`, these functions don't do refcount operations on them either.

## Thread Specific Storage (TSS) API

TSS API is introduced to supersede the use of the existing TLS API within the CPython interpreter. This API uses a new type `Py_tss_t` instead of int to represent thread keys.

*New in version 3.7.*

## See also

“A New C-API for Thread-Local Storage in CPython” ([PEP 539](https://peps.python.org/pep-0539/))  
[<https://peps.python.org/pep-0539/>]

type `Py_tss_t`

This data structure represents the state of a thread key, the definition of which may depend on the underlying TLS implementation, and it has an internal field representing the key’s initialization state. There are no public members in this structure.

When `Py_LIMITED_API` is not defined, static allocation of this type by `Py_tss_NEEDS_INIT` is allowed.

`Py_tss_NEEDS_INIT`

This macro expands to the initializer for `Py_tss_t` variables. Note that this macro won’t be defined with `Py_LIMITED_API`.

## Dynamic Allocation

Dynamic allocation of the `Py_tss_t`, required in extension modules built with `Py_LIMITED_API`, where static allocation of this type is not possible due to its implementation being opaque at build time.

`Py_tss_t *PyThread_tss_alloc()`

*Part of the [Stable ABI](#) since version 3.7.*

Return a value which is the same state as a value initialized with `Py_tss_NEEDS_INIT`, or `NULL` in the case of dynamic allocation failure.

`void PyThread_tss_free(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Free the given `key` allocated by `PyThread_tss_alloc()`,

after first calling `PyThread_tss_delete()` to ensure any associated thread locals have been unassigned. This is a no-op if the `key` argument is `NULL`.

## Note

A freed key becomes a dangling pointer. You should reset the key to `NULL`.

## Methods

The parameter `key` of these functions must not be `NULL`. Moreover, the behaviors of `PyThread_tss_set()` and `PyThread_tss_get()` are undefined if the given `Py_tss_t` has not been initialized by `PyThread_tss_create()`.

`int PyThread_tss_is_created(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Return a non-zero value if the given `Py_tss_t` has been initialized by `PyThread_tss_create()`.

`int PyThread_tss_create(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Return a zero value on successful initialization of a TSS key. The behavior is undefined if the value pointed to by the `key` argument is not initialized by `Py_tss_NEEDS_INIT`. This function can be called repeatedly on the same key – calling it on an already initialized key is a no-op and immediately returns success.

`void PyThread_tss_delete(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Destroy a TSS key to forget the values associated with the key across all threads, and change the key's initialization state to uninitialized. A destroyed key is able to be initialized again by `PyThread_tss_create()`. This function can be called repeatedly on the same key – calling it on an already

destroyed key is a no-op.

```
int PyThread_tss_set(Py_tss_t *key, void *value)
```

*Part of the [Stable ABI](#) since version 3.7.*

Return a zero value to indicate successfully associating a void\* value with a TSS key in the current thread. Each thread has a distinct mapping of the key to a void\* value.

```
void *PyThread_tss_get(Py_tss_t *key)
```

*Part of the [Stable ABI](#) since version 3.7.*

Return the void\* value associated with a TSS key in the current thread. This returns NULL if no value is associated with the key in the current thread.

## Thread Local Storage (TLS) API

*Deprecated since version 3.7:* This API is superseded by [Thread Specific Storage \(TSS\) API](#).

### Note

This version of the API does not support platforms where the native TLS key is defined in a way that cannot be safely cast to `int`. On such platforms, `PyThread_create_key()` will return immediately with a failure status, and the other TLS functions will all be no-ops on such platforms.

Due to the compatibility problem noted above, this version of the API should not be used in new code.

```
int PyThread_create_key()
```

*Part of the [Stable ABI](#).*

```
void PyThread_delete_key(int key)
```

*Part of the [Stable ABI](#).*

```
int PyThread_set_key_value(int key, void *value)
```

*Part of the [Stable ABI](#).*

`void *PyThread_get_key_value(int key)`

*Part of the [Stable ABI](#).*

`void PyThread_delete_key_value(int key)`

*Part of the [Stable ABI](#).*

`void PyThread_ReInitTLS()`

*Part of the [Stable ABI](#).*

# Python Initialization Configuration

*New in version 3.8.*

Python can be initialized with `Py_InitializeFromConfig()` and the `PyConfig` structure. It can be preinitialized with `Py_PreInitialize()` and the `PyPreConfig` structure.

There are two kinds of configuration:

- The [Python Configuration](#) can be used to build a customized Python which behaves as the regular Python. For example, environment variables and command line arguments are used to configure Python.
- The [Isolated Configuration](#) can be used to embed Python into an application. It isolates Python from the system. For example, environment variables are ignored, the LC\_CTYPE locale is left unchanged and no signal handler is registered.

The `Py_RunMain()` function can be used to write a customized Python program.

See also [Initialization](#), [Finalization](#), and [Threads](#).

**See also**

**PEP 587** [<https://peps.python.org/pep-0587/>] “Python Initialization Configuration”.

## Example

Example of customized Python always running in isolated mode:

```
int main(int argc, char **argv)
```

```

{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);
    config.isolated = 1;

    /* Decode command line arguments.
       Implicitly preinitialize Python (in isolated mode)
    status = PyConfig_SetBytesArgv(&config, argc, argv);
    if (PyStatus_Exception(status)) {
        goto exception;
    }

    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);

    return Py_RunMain();

exception:
    PyConfig_Clear(&config);
    if (PyStatus_IsExit(status)) {
        return status.exitcode;
    }
    /* Display the error message and exit the process with
       non-zero exit code */
    Py_ExitStatusException(status);
}

```

## PyWideStringList

type PyWideStringList

List of `wchar_t*` strings.

If *length* is non-zero, *items* must be non-NULL and all strings

must be non-NULL.

Methods:

**PyStatus** PyWideStringList\_Append(**PyWideStringList** \*list,  
const wchar\_t \*item)

Append *item* to *list*.

Python must be preinitialized to call this function.

**PyStatus** PyWideStringList\_Insert(**PyWideStringList** \*list,  
**Py\_ssize\_t** index, const wchar\_t \*item)

Insert *item* into *list* at *index*.

If *index* is greater than or equal to *list* length, append *item* to *list*.

*index* must be greater than or equal to 0.

Python must be preinitialized to call this function.

Structure fields:

**Py\_ssize\_t** length  
List length.

wchar\_t \*\*items  
List items.

## PyStatus

type PyStatus

Structure to store an initialization function status: success, error or exit.

For an error, it can store the C function name which created the error.

Structure fields:

`int exitcode`

Exit code. Argument passed to `exit()`.

`const char *err_msg`

Error message.

`const char *func`

Name of the function which created an error, can be `NULL`.

Functions to create a status:

`PyStatus` `PyStatus_Ok(void)`

Success.

`PyStatus` `PyStatus_Error(const char *err_msg)`

Initialization error with a message.

*err\_msg* must not be `NULL`.

`PyStatus` `PyStatus_NoMemory(void)`

Memory allocation failure (out of memory).

`PyStatus` `PyStatus_Exit(int exitcode)`

Exit Python with the specified exit code.

Functions to handle a status:

`int` `PyStatus_Exception(PyStatus status)`

Is the status an error or an exit? If true, the exception must be handled; by calling

`Py_ExitStatusException()` for example.

`int` `PyStatus_IsError(PyStatus status)`

Is the result an error?

`int PyStatus_IsExit(PyStatus status)`

Is the result an exit?

`void Py_ExitStatusException(PyStatus status)`

Call `exit(exitcode)` if *status* is an exit. Print the error message and exit with a non-zero exit code if *status* is an error. Must only be called if `PyStatus_Exception(status)` is non-zero.

## Note

Internally, Python uses macros which set `PyStatus.func`, whereas functions to create a status set `func` to `NULL`.

## Example:

```
PyStatus alloc(void **ptr, size_t size)
{
    *ptr = PyMem_RawMalloc(size);
    if (*ptr == NULL) {
        return PyStatus_NoMemory();
    }
    return PyStatus_Ok();
}

int main(int argc, char **argv)
{
    void *ptr;
    PyStatus status = alloc(&ptr, 16);
    if (PyStatus_Exception(status)) {
        Py_ExitStatusException(status);
    }
    PyMem_Free(ptr);
    return 0;
}
```

# PyPreConfig

type PyPreConfig

Structure used to preinitialize Python.

Function to initialize a preconfiguration:

void PyPreConfig\_InitPythonConfig(PyPreConfig \*preconfig)

Initialize the preconfiguration with [Python Configuration](#).

void PyPreConfig\_InitIsolatedConfig(PyPreConfig \*preconfig)

Initialize the preconfiguration with [Isolated Configuration](#).

Structure fields:

int allocator

Name of the Python memory allocators:

- PYMEM\_ALLOCATOR\_NOT\_SET (0): don't change memory allocators (use defaults).
- PYMEM\_ALLOCATOR\_DEFAULT (1): [default memory allocators](#).
- PYMEM\_ALLOCATOR\_DEBUG (2): [default memory allocators with debug hooks](#).
- PYMEM\_ALLOCATOR\_MALLOC (3): use `malloc()` of the C library.
- PYMEM\_ALLOCATOR\_MALLOC\_DEBUG (4): force usage of `malloc()` with [debug hooks](#).
- PYMEM\_ALLOCATOR\_PYMALLOC (5): [Python pymalloc memory allocator](#).
- PYMEM\_ALLOCATOR\_PYMALLOC\_DEBUG (6): [Python pymalloc memory allocator with debug hooks](#).

PYMEM\_ALLOCATOR\_PYMALLOC and PYMEM\_ALLOCATOR\_PYMALLOC\_DEBUG are not supported if Python is [configured using --](#)

`without-pymalloc`.

See [Memory Management](#).

Default: `PYMEM_ALLOCATOR_NOT_SET`.

`int configure_locale`

Set the `LC_CTYPE` locale to the user preferred locale.

If equals to `0`, set `coerce_c_locale` and `coerce_c_locale_warn` members to `0`.

See the [locale encoding](#).

Default: `1` in Python config, `0` in isolated config.

`int coerce_c_locale`

If equals to `2`, coerce the C locale.

If equals to `1`, read the `LC_CTYPE` locale to decide if it should be coerced.

See the [locale encoding](#).

Default: `-1` in Python config, `0` in isolated config.

`int coerce_c_locale_warn`

If non-zero, emit a warning if the C locale is coerced.

Default: `-1` in Python config, `0` in isolated config.

`int dev_mode`

[Python Development Mode](#): see `PyConfig.dev_mode`.

Default: `-1` in Python mode, `0` in isolated mode.

`int isolated`

Isolated mode: see `PyConfig.isolated`.

Default: 0 in Python mode, 1 in isolated mode.

int legacy\_windows\_fs\_encoding

If non-zero:

- Set `PyPreConfig.utf8_mode` to 0,
- Set `PyConfig.filesystem_encoding` to "mbcs",
- Set `PyConfig.filesystem_errors` to "replace".

Initialized the from

`PYTHONLEGACYWINDOWSFSENCODING` environment variable value.

Only available on Windows. `#ifdef MS_WINDOWS` macro can be used for Windows specific code.

Default: 0.

int parse\_argv

If non-zero, `Py_PreInitializeFromArgs()` and `Py_PreInitializeFromBytesArgs()` parse their argv argument the same way the regular Python parses command line arguments: see [Command Line Arguments](#).

Default: 1 in Python config, 0 in isolated config.

int use\_environment

Use [environment variables](#)? See `PyConfig.use_environment`.

Default: 1 in Python config and 0 in isolated config.

int utf8\_mode

If non-zero, enable the [Python UTF-8 Mode](#).

Set to 0 or 1 by the `-X utf8` command line option and the `PYTHONUTF8` environment variable.

Also set to 1 if the LC\_CTYPE locale is C or POSIX.

Default: -1 in Python config and 0 in isolated config.

## Preinitialize Python with PyPreConfig

The preinitialization of Python:

- Set the Python memory allocators (`PyPreConfig.allocators`)
- Configure the LC\_CTYPE locale (`locale encoding`)
- Set the `Python UTF-8 Mode` (`PyPreConfig.utf8_mode`)

The current preconfiguration (PyPreConfig type) is stored in `_PyRuntime.preconfig`.

Functions to preinitialize Python:

`PyStatus` `Py_PreInitialize(const PyPreConfig *preconfig)`

Preinitialize Python from *preconfig* preconfiguration.

*preconfig* must not be `NULL`.

`PyStatus` `Py_PreInitializeFromBytesArgs(const PyPreConfig *preconfig, int argc, char *const *argv)`

Preinitialize Python from *preconfig* preconfiguration.

Parse *argv* command line arguments (bytes strings) if `parse_argv` of *preconfig* is non-zero.

*preconfig* must not be `NULL`.

`PyStatus` `Py_PreInitializeFromArgs(const PyPreConfig *preconfig, int argc, wchar_t *const *argv)`

Preinitialize Python from *preconfig* preconfiguration.

Parse *argv* command line arguments (wide strings) if `parse_argv` of *preconfig* is non-zero.

*preconfig* must not be `NULL`.

The caller is responsible to handle exceptions (error or exit) using `PyStatus_Exception()` and `Py_ExitStatusException()`.

For [Python Configuration](#)

(`PyPreConfig_InitPythonConfig()`), if Python is initialized with command line arguments, the command line arguments must also be passed to preinitialize Python, since they have an effect on the pre-configuration like encodings. For example, the `-X utf8` command line option enables the [Python UTF-8 Mode](#).

`PyMem_SetAllocator()` can be called after `Py_PreInitialize()` and before `Py_InitializeFromConfig()` to install a custom memory allocator. It can be called before `Py_PreInitialize()` if `PyPreConfig.allocator` is set to `PYMEM_ALLOCATOR_NOT_SET`.

Python memory allocation functions like `PyMem_RawMalloc()` must not be used before the Python preinitialization, whereas calling directly `malloc()` and `free()` is always safe. `Py_DecodeLocale()` must not be called before the Python preinitialization.

Example using the preinitialization to enable the [Python UTF-8 Mode](#):

```
PyStatus status;
PyPreConfig preconfig;
PyPreConfig_InitPythonConfig(&preconfig);

preconfig.utf8_mode = 1;

status = Py_PreInitialize(&preconfig);
if (PyStatus_Exception(status)) {
    Py_ExitStatusException(status);
}

/* at this point, Python speaks UTF-8 */
```

```
Py_Initialize();  
/* ... use Python API here ... */  
Py_Finalize();
```

## PyConfig

type PyConfig

Structure containing most parameters to configure Python.

When done, the [PyConfig\\_Clear\(\)](#) function must be used to release the configuration memory.

Structure methods:

`void PyConfig_InitPythonConfig(PyConfig *config)`

Initialize configuration with the [Python Configuration](#).

`void PyConfig_InitIsolatedConfig(PyConfig *config)`

Initialize configuration with the [Isolated Configuration](#).

[PyStatus](#) `PyConfig_SetString(PyConfig *config, wchar_t *const *config_str, const wchar_t *str)`

Copy the wide character string *str* into *\*config\_str*.

[Preinitialize Python](#) if needed.

[PyStatus](#) `PyConfig_SetBytesString(PyConfig *config, wchar_t *const *config_str, const char *str)`

Decode *str* using [Py\\_DecodeLocale\(\)](#) and set the result into *\*config\_str*.

[Preinitialize Python](#) if needed.

[PyStatus](#) `PyConfig_SetArgv(PyConfig *config, int argc, wchar_t *const *argv)`

Set command line arguments ([argv](#) member of *config*)

from the *argv* list of wide character strings.

Preinitialize Python if needed.

**PyStatus** PyConfig\_SetBytesArgv(**PyConfig** \*config, int argc, char \*const \*argv)

Set command line arguments (**argv** member of *config*) from the *argv* list of bytes strings. Decode bytes using **Py\_DecodeLocale()**.

Preinitialize Python if needed.

**PyStatus** PyConfig\_SetWideStringList(**PyConfig** \*config, PyWideStringList \*list, **Py\_ssize\_t** length, wchar\_t \*\*items)

Set the list of wide strings *list* to *length* and *items*.

Preinitialize Python if needed.

**PyStatus** PyConfig\_Read(**PyConfig** \*config)

Read all Python configuration.

Fields which are already initialized are left unchanged.

Fields for **path configuration** are no longer calculated or modified when calling this function, as of Python 3.11.

The **PyConfig\_Read()** function only parses **PyConfig.argv** arguments once: **PyConfig.parse\_argv** is set to 2 after arguments are parsed. Since Python arguments are stripped from **PyConfig.argv**, parsing arguments twice would parse the application options as Python options.

Preinitialize Python if needed.

*Changed in version 3.10:* The **PyConfig.argv** arguments are now only parsed once, **PyConfig.parse\_argv** is set to 2 after arguments are parsed, and arguments are only parsed if

`PyConfig.parse_argv` equals 1.

*Changed in version 3.11:* `PyConfig_Read()` no longer calculates all paths, and so fields listed under [Python Path Configuration](#) may no longer be updated until `Py_InitializeFromConfig()` is called.

`void PyConfig_Clear(PyConfig *config)`

Release configuration memory.

Most `PyConfig` methods [preinitialize Python](#) if needed. In that case, the Python preinitialization configuration (`PyPreConfig`) is based on the `PyConfig`. If configuration fields which are in common with `PyPreConfig` are tuned, they must be set before calling a `PyConfig` method:

- `PyConfig.dev_mode`
- `PyConfig.isolated`
- `PyConfig.parse_argv`
- `PyConfig.use_environment`

Moreover, if `PyConfig_SetArgv()` or `PyConfig_SetBytesArgv()` is used, this method must be called before other methods, since the preinitialization configuration depends on command line arguments (if `parse_argv` is non-zero).

The caller of these methods is responsible to handle exceptions (error or exit) using `PyStatus_Exception()` and `Py_ExitStatusException()`.

Structure fields:

`PyWideStringList argv`

Command line arguments: `sys.argv`.

Set `parse_argv` to 1 to parse `argv` the same way the regular Python parses Python command line arguments and then to strip Python arguments from `argv`.

If `argv` is empty, an empty string is added to ensure that `sys.argv` always exists and is never empty.

Default: `NULL`.

See also the `orig_argv` member.

`int safe_path`

If equals to zero, `Py_RunMain()` prepends a potentially unsafe path to `sys.path` at startup:

- If `argv[0]` is equal to `L"-m"` (`python -m module`), prepend the current working directory.
- If running a script (`python script.py`), prepend the script's directory. If it's a symbolic link, resolve symbolic links.
- Otherwise (`python -c code` and `python`), prepend an empty string, which means the current working directory.

Set to `1` by the `-P` command line option and the `PYTHONSAFEPATH` environment variable.

Default: `0` in Python config, `1` in isolated config.

*New in version 3.11.*

`wchar_t *base_exec_prefix`

`sys.base_exec_prefix`.

Default: `NULL`.

Part of the [Python Path Configuration](#) output.

`wchar_t *base_executable`

Python base executable: `sys._base_executable`.

Set by the `__PYENVV_LAUNCHER__` environment variable.

Set from `PyConfig.executable` if `NULL`.

Default: `NULL`.

Part of the [Python Path Configuration](#) output.

`wchar_t *base_prefix`  
[`sys.base\_prefix`](#).

Default: `NULL`.

Part of the [Python Path Configuration](#) output.

`int buffered_stdio`

If equals to `0` and [`configure\_c\_stdio`](#) is non-zero, disable buffering on the C streams `stdout` and `stderr`.

Set to `0` by the [`-u`](#) command line option and the [`PYTHONUNBUFFERED`](#) environment variable.

`stdin` is always opened in buffered mode.

Default: `1`.

`int bytes_warning`

If equals to `1`, issue a warning when comparing [`bytes`](#) or [`bytearray`](#) with [`str`](#), or comparing [`bytes`](#) with [`int`](#).

If equal or greater to `2`, raise a [`BytesWarning`](#) exception in these cases.

Incremented by the [`-b`](#) command line option.

Default: `0`.

`int warn_default_encoding`

If non-zero, emit a [`EncodingWarning`](#) warning when [`io.TextIOWrapper`](#) uses its default encoding. See [Opt-in EncodingWarning](#) for details.

Default: `0`.

*New in version 3.10.*

`int code_debug_ranges`

If equals to 0, disables the inclusion of the end line and column mappings in code objects. Also disables traceback printing carets to specific error locations.

Set to 0 by the `PYTHONNODEBUGRANGES` environment variable and by the `-X no_debug_ranges` command line option.

Default: 1.

*New in version 3.11.*

`wchar_t *check_hash_pycs_mode`

Control the validation behavior of hash-based .pyc files: value of the `--check-hash-based-pycs` command line option.

Valid values:

- `L"always"`: Hash the source file for invalidation regardless of value of the ‘check\_source’ flag.
- `L"never"`: Assume that hash-based pycs always are valid.
- `L"default"`: The ‘check\_source’ flag in hash-based pycs determines invalidation.

Default: `L"default"`.

See also [PEP 552](https://peps.python.org/pep-0552/) [https://peps.python.org/pep-0552/] “Deterministic pycs”.

`int configure_c_stdio`

If non-zero, configure C standard streams:

- On Windows, set the binary mode (`O_BINARY`) on stdin, stdout and stderr.
- If `buffered_stdio` equals zero, disable

- buffering of stdin, stdout and stderr streams.
- If **interactive** is non-zero, enable stream buffering on stdin and stdout (only stdout on Windows).

Default: 1 in Python config, 0 in isolated config.

int dev\_mode

If non-zero, enable the [Python Development Mode](#).

Set to 1 by the **-X dev** option and the **PYTHONDEVMODE** environment variable.

Default: -1 in Python mode, 0 in isolated mode.

int dump\_refs

Dump Python references?

If non-zero, dump all objects which are still alive at exit.

Set to 1 by the **PYTHONDUMPREFS** environment variable.

Need a special build of Python with the **Py\_TRACE\_REFS** macro defined: see the [configure --with-trace-refs option](#).

Default: 0.

wchar\_t \*exec\_prefix

The site-specific directory prefix where the platform-dependent Python files are installed:

[sys.exec\\_prefix](#).

Default: NULL.

Part of the [Python Path Configuration](#) output.

wchar\_t \*executable

The absolute path of the executable binary for the Python interpreter: `sys.executable`.

Default: NULL.

Part of the [Python Path Configuration](#) output.

`int` `faulthandler`

Enable `faulthandler`?

If non-zero, call `faulthandler.enable()` at startup.

Set to 1 by `-X faulthandler` and the `PYTHONFAULTHANDLER` environment variable.

Default: -1 in Python mode, 0 in isolated mode.

`wchar_t *``filesystem_encoding`

[Filesystem encoding](#):

`sys.getfilesystemencoding()`.

On macOS, Android and VxWorks: use "utf-8" by default.

On Windows: use "utf-8" by default, or "mbcs" if [legacy\\_windows\\_fs\\_encoding](#) of `PyPreConfig` is non-zero.

Default encoding on other platforms:

- "utf-8" if `PyPreConfig.utf8_mode` is non-zero.
- "ascii" if Python detects that `nl_langinfo(CODESET)` announces the ASCII encoding, whereas the `mbstowcs()` function decodes from a different encoding (usually Latin1).
- "utf-8" if `nl_langinfo(CODESET)` returns an empty string.
- Otherwise, use the [locale encoding](#):

`nl_langinfo(CODESET)` result.

At Python startup, the encoding name is normalized to the Python codec name. For example, "ANSI\_X3.4-1968" is replaced with "ascii".

See also the `filesystem_errors` member.

`wchar_t *filesystem_errors`

Filesystem error handler:

`sys.getfilesystemencodeerrors()`.

On Windows: use "surrogatepass" by default, or "replace" if `legacy_windows_fs_encoding` of `PyPreConfig` is non-zero.

On other platforms: use "surrogateescape" by default.

Supported error handlers:

- "strict"
- "surrogateescape"
- "surrogatepass" (only supported with the UTF-8 encoding)

See also the `filesystem_encoding` member.

`unsigned long hash_seed`

`int use_hash_seed`

Randomized hash function seed.

If `use_hash_seed` is zero, a seed is chosen randomly at Python startup, and `hash_seed` is ignored.

Set by the `PYTHONHASHSEED` environment variable.

Default `use_hash_seed` value: -1 in Python mode, 0 in isolated mode.

wchar\_t \*home

Python home directory.

If `Py_SetPythonHome()` has been called, use its argument if it is not `NULL`.

Set by the `PYTHONHOME` environment variable.

Default: `NULL`.

Part of the [Python Path Configuration](#) input.

int import\_time

If non-zero, profile import time.

Set the `1` by the `-X importtime` option and the `PYTHONPROFILEIMPORTTIME` environment variable.

Default: `0`.

int inspect

Enter interactive mode after executing a script or a command.

If greater than `0`, enable inspect: when a script is passed as first argument or the `-c` option is used, enter interactive mode after executing the script or the command, even when `sys.stdin` does not appear to be a terminal.

Incremented by the `-i` command line option. Set to `1` if the `PYTHONINSPECT` environment variable is non-empty.

Default: `0`.

int install\_signal\_handlers

Install Python signal handlers?

Default: `1` in Python mode, `0` in isolated mode.

## int interactive

If greater than 0, enable the interactive mode (REPL).

Incremented by the `-i` command line option.

Default: 0.

## int int\_max\_str\_digits

Configures the [integer string conversion length limitation](#). An initial value of -1 means the value will be taken from the command line or environment or otherwise default to 4300

(`sys.int_info.default_max_str_digits`). A value of 0 disables the limitation. Values greater than zero but less than 640

(`sys.int_info.str_digits_check_threshold`) are unsupported and will produce an error.

Configured by the `-X int_max_str_digits` command line flag or the `PYTHONINTMAXSTRDIGITS` environment variable.

Default: -1 in Python mode. 4300

(`sys.int_info.default_max_str_digits`) in isolated mode.

*New in version 3.12.*

## int isolated

If greater than 0, enable isolated mode:

- Set `safe_path` to 1: don't prepend a potentially unsafe path to `sys.path` at Python startup, such as the current directory, the script's directory or an empty string.
- Set `use_environment` to 0: ignore PYTHON environment variables.
- Set `user_site_directory` to 0: don't add the user site directory to `sys.path`.
- Python REPL doesn't import `readline` nor

enable default readline configuration on interactive prompts.

Set to 1 by the `-I` command line option.

Default: 0 in Python mode, 1 in isolated mode.

See also the [Isolated Configuration](#) and `PyPreConfig.isolated`.

`int legacy_windows_stdio`

If non-zero, use `io.FileIO` instead of `io._WindowsConsoleIO` for `sys.stdin`, `sys.stdout` and `sys.stderr`.

Set to 1 if the `PYTHONLEGACYWINDOWSSTDIO` environment variable is set to a non-empty string.

Only available on Windows. `#ifdef MS_WINDOWS` macro can be used for Windows specific code.

Default: 0.

See also the [PEP 528](https://peps.python.org/pep-0528/) [https://peps.python.org/pep-0528/] (Change Windows console encoding to UTF-8).

`int malloc_stats`

If non-zero, dump statistics on [Python pymalloc memory allocator](#) at exit.

Set to 1 by the `PYTHONMALLOCSTATS` environment variable.

The option is ignored if Python is [configured using the `--without-pymalloc` option](#).

Default: 0.

`wchar_t *platlibdir`

Platform library directory name: `sys.platlibdir`.

Set by the `PYTHONPLATLIBDIR` environment variable.

Default: value of the `PLATLIBDIR` macro which is set by the `configure --with-platlibdir option` (default: `"lib"`, or `"DLLs"` on Windows).

Part of the [Python Path Configuration](#) input.

*New in version 3.9.*

*Changed in version 3.11:* This macro is now used on Windows to locate the standard library extension modules, typically under `DLLs`. However, for compatibility, note that this value is ignored for any non-standard layouts, including in-tree builds and virtual environments.

`wchar_t *pythonpath_env`

Module search paths (`sys.path`) as a string separated by `DELIM` (`os.pathsep`).

Set by the `PYTHONPATH` environment variable.

Default: `NULL`.

Part of the [Python Path Configuration](#) input.

[PyWideStringList](#) `module_search_paths`

`int module_search_paths_set`

Module search paths: `sys.path`.

If `module_search_paths_set` is equal to `0`, `Py_InitializeFromConfig()` will replace `module_search_paths` and sets `module_search_paths_set` to `1`.

Default: empty list (`module_search_paths`) and `0` (`module_search_paths_set`).

Part of the [Python Path Configuration](#) output.

int optimization\_level

Compilation optimization level:

- 0: Peephole optimizer, set `__debug__` to `True`.
- 1: Level 0, remove assertions, set `__debug__` to `False`.
- 2: Level 1, strip docstrings.

Incremented by the `-O` command line option. Set to the `PYTHONOPTIMIZE` environment variable value.

Default: 0.

PyWideStringList orig\_argv

The list of the original command line arguments passed to the Python executable: `sys.orig_argv`.

If `orig_argv` list is empty and `argv` is not a list only containing an empty string, `PyConfig_Read()` copies `argv` into `orig_argv` before modifying `argv` (if `parse_argv` is non-zero).

See also the `argv` member and the `Py_GetArgcArgv()` function.

Default: empty list.

*New in version 3.10.*

int parse\_argv

Parse command line arguments?

If equals to 1, parse `argv` the same way the regular Python parses `command line arguments`, and strip Python arguments from `argv`.

The `PyConfig_Read()` function only parses `PyConfig.argv` arguments once: `PyConfig.parse_argv` is set to 2 after arguments are parsed. Since Python arguments are stripped from `PyConfig.argv`, parsing arguments twice would

parse the application options as Python options.

Default: 1 in Python mode, 0 in isolated mode.

*Changed in version 3.10:* The `PyConfig.argv` arguments are now only parsed if `PyConfig.parse_argv` equals to 1.

`int parser_debug`

Parser debug mode. If greater than 0, turn on parser debugging output (for expert only, depending on compilation options).

Incremented by the `-d` command line option. Set to the `PYTHONDEBUG` environment variable value.

Need a `debug build of Python` (the `Py_DEBUG` macro must be defined).

Default: 0.

`int pathconfig_warnings`

If non-zero, calculation of path configuration is allowed to log warnings into `stderr`. If equals to 0, suppress these warnings.

Default: 1 in Python mode, 0 in isolated mode.

Part of the `Python Path Configuration` input.

*Changed in version 3.11:* Now also applies on Windows.

`wchar_t *prefix`

The site-specific directory prefix where the platform independent Python files are installed: `sys.prefix`.

Default: `NULL`.

Part of the `Python Path Configuration` output.

wchar\_t \*program\_name

Program name used to initialize **executable** and in early error messages during Python initialization.

- If **Py\_SetProgramName()** has been called, use its argument.
- On macOS, use **PYTHONEXECUTABLE** environment variable if set.
- If the **WITH\_NEXT\_FRAMEWORK** macro is defined, use **\_\_PYENV\_LAUNCHER\_\_** environment variable if set.
- Use **argv[0]** of **argv** if available and non-empty.
- Otherwise, use **L"python"** on Windows, or **L"python3"** on other platforms.

Default: **NULL**.

Part of the **Python Path Configuration** input.

wchar\_t \*pycache\_prefix

Directory where cached **.pyc** files are written:  
**sys.pycache\_prefix**.

Set by the **-X pycache\_prefix=PATH** command line option and the **PYTHONPYCACHEPREFIX** environment variable.

If **NULL**, **sys.pycache\_prefix** is set to **None**.

Default: **NULL**.

int quiet

Quiet mode. If greater than **0**, don't display the copyright and version at Python startup in interactive mode.

Incremented by the **-q** command line option.

Default: **0**.

wchar\_t \*run\_command

Value of the `-c` command line option.

Used by `Py_RunMain()`.

Default: `NULL`.

wchar\_t \*run\_filename

Filename passed on the command line: trailing command line argument without `-c` or `-m`. It is used by the `Py_RunMain()` function.

For example, it is set to `script.py` by the `python3 script.py arg` command line.

See also the `PyConfig.skip_source_first_line` option.

Default: `NULL`.

wchar\_t \*run\_module

Value of the `-m` command line option.

Used by `Py_RunMain()`.

Default: `NULL`.

int show\_ref\_count

Show total reference count at exit (excluding immortal objects)?

Set to 1 by `-X showrefcount` command line option.

Need a [debug build of Python](#) (the `Py_REF_DEBUG` macro must be defined).

Default: 0.

int site\_import

Import the `site` module at startup?

If equal to zero, disable the import of the module `site` and the site-dependent manipulations of `sys.path` that it entails.

Also disable these manipulations if the `site` module is explicitly imported later (call `site.main()` if you want them to be triggered).

Set to 0 by the `-S` command line option.

`sys.flags.no_site` is set to the inverted value of `site_import`.

Default: 1.

`int skip_source_first_line`

If non-zero, skip the first line of the `PyConfig.run_filename` source.

It allows the usage of non-Unix forms of `#!cmd`. This is intended for a DOS specific hack only.

Set to 1 by the `-x` command line option.

Default: 0.

`wchar_t *stdio_encoding`

`wchar_t *stdio_errors`

Encoding and encoding errors of `sys.stdin`, `sys.stdout` and `sys.stderr` (but `sys.stderr` always uses "backslashreplace" error handler).

If `Py_SetStandardStreamEncoding()` has been called, use its *error* and *errors* arguments if they are not NULL.

Use the `PYTHONIOENCODING` environment variable if it is non-empty.

Default encoding:

- "UTF-8" if `PyPreConfig.utf8_mode` is non-zero.
- Otherwise, use the [locale encoding](#).

Default error handler:

- On Windows: use "surrogateescape".
- "surrogateescape" if `PyPreConfig.utf8_mode` is non-zero, or if the LC\_CTYPE locale is "C" or "POSIX".
- "strict" otherwise.

`int tracemalloc`

Enable tracemalloc?

If non-zero, call `tracemalloc.start()` at startup.

Set by `-X tracemalloc=N` command line option and by the `PYTHONTRACEMALLOC` environment variable.

Default: -1 in Python mode, 0 in isolated mode.

`int perf_profiling`

Enable compatibility mode with the perf profiler?

If non-zero, initialize the perf trampoline. See [Python support for the Linux perf profiler](#) for more information.

Set by `-X perf` command line option and by the `PYTHONPERFSUPPORT` environment variable.

Default: -1.

*New in version 3.12.*

`int use_environment`

Use [environment variables](#)?

If equals to zero, ignore the [environment variables](#).

Set to 0 by the **-E** environment variable.

Default: 1 in Python config and 0 in isolated config.

int user\_site\_directory

If non-zero, add the user site directory to **sys.path**.

Set to 0 by the **-s** and **-I** command line options.

Set to 0 by the **PYTHONNOUSERSITE** environment variable.

Default: 1 in Python mode, 0 in isolated mode.

int verbose

Verbose mode. If greater than 0, print a message each time a module is imported, showing the place (filename or built-in module) from which it is loaded.

If greater than or equal to 2, print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit.

Incremented by the **-v** command line option.

Set by the **PYTHONVERBOSE** environment variable value.

Default: 0.

**PyWideStringList** warnoptions

Options of the **warnings** module to build warnings filters, lowest to highest priority: **sys.warnoptions**.

The **warnings** module adds **sys.warnoptions** in the reverse order: the last **PyConfig.warnoptions** item becomes the first item of **warnings.filters** which is checked first (highest priority).

The **-W** command line options adds its value to **warnoptions**, it can be used multiple times.

The `PYTHONWARNINGS` environment variable can also be used to add warning options. Multiple options can be specified, separated by commas (,).

Default: empty list.

`int write_bytecode`

If equal to 0, Python won't try to write `.pyc` files on the import of source modules.

Set to 0 by the `-B` command line option and the `PYTHONDONTWRITEBYTECODE` environment variable.

`sys.dont_write_bytecode` is initialized to the inverted value of `write_bytecode`.

Default: 1.

`PyWideStringList xoptions`

Values of the `-X` command line options:

`sys._xoptions`.

Default: empty list.

If `parse_argv` is non-zero, `argv` arguments are parsed the same way the regular Python parses [command line arguments](#), and Python arguments are stripped from `argv`.

The `xoptions` options are parsed to set other options: see the `-X` command line option.

*Changed in version 3.9:* The `show_alloc_count` field has been removed.

## Initialization with PyConfig

Function to initialize Python:

`PyStatus Py_InitializeFromConfig(const PyConfig *config)`

Initialize Python from *config* configuration.

The caller is responsible to handle exceptions (error or exit) using `PyStatus_Exception()` and `Py_ExitStatusException()`.

If `PyImport_FrozenModules()`, `PyImport_AppendInittab()` or `PyImport_ExtendInittab()` are used, they must be set or called after Python preinitialization and before the Python initialization. If Python is initialized multiple times, `PyImport_AppendInittab()` or `PyImport_ExtendInittab()` must be called before each Python initialization.

The current configuration (PyConfig type) is stored in `PyInterpreterState.config`.

Example setting the program name:

```
void init_python(void)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* Set the program name. Implicitly preinitialize Py
    status = PyConfig_SetString(&config, &config.program_name,
                                L"/path/to/my_program");
    if (PyStatus_Exception(status)) {
        goto exception;
    }

    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);
    return;
```

```

exception:
    PyConfig_Clear(&config);
    Py_ExitStatusException(status);
}

```

More complete example modifying the default configuration, read the configuration, and then override some parameters. Note that since 3.11, many parameters are not calculated until initialization, and so values cannot be read from the configuration structure. Any values set before initialize is called will be left unchanged by initialization:

```

PyStatus init_python(const char *program_name)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* Set the program name before reading the configuration
       (decode byte string from the locale encoding).

       Implicitly preinitialize Python. */
    status = PyConfig_SetBytesString(&config, &config.program_name,
                                     program_name);
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Read all configuration at once */
    status = PyConfig_Read(&config);
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Specify sys.path explicitly */
    /* If you want to modify the default set of paths, first do
       initialization first and then use PySys_GetObject
       config.module_search_paths_set = 1;

```

```

        status = PyWideStringList_Append(&config.module_search_path,
   L"/path/to/stdlib")
    if (PyStatus_Exception(status)) {
        goto done;
    }
    status = PyWideStringList_Append(&config.module_search_path,
                                     L"/path/to/more/modules")
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Override executable computed by PyConfig_Read() */
    status = PyConfig_SetString(&config, &config.executable,
                               L"/path/to/my_executable")
    if (PyStatus_Exception(status)) {
        goto done;
    }

    status = Py_InitializeFromConfig(&config);

done:
    PyConfig_Clear(&config);
    return status;
}

```

## Isolated Configuration

**PyPreConfig\_InitIsolatedConfig()** and **PyConfig\_InitIsolatedConfig()** functions create a configuration to isolate Python from the system. For example, to embed Python into an application.

This configuration ignores global configuration variables, environment variables, command line arguments (**PyConfig.argv** is not parsed) and user site directory. The C standard streams (ex: stdout) and the LC\_CTYPE locale are left unchanged. Signal handlers are not installed.

Configuration files are still used with this configuration to

determine paths that are unspecified. Ensure `PyConfig.home` is specified to avoid computing the default path configuration.

## Python Configuration

`PyPreConfig_InitPythonConfig()` and `PyConfig_InitPythonConfig()` functions create a configuration to build a customized Python which behaves as the regular Python.

Environments variables and command line arguments are used to configure Python, whereas global configuration variables are ignored.

This function enables C locale coercion ([PEP 538](https://peps.python.org/pep-0538/) [https://peps.python.org/pep-0538/]) and [Python UTF-8 Mode](https://peps.python.org/pep-0540/) ([PEP 540](https://peps.python.org/pep-0540/) [https://peps.python.org/pep-0540/]) depending on the `LC_CTYPE` locale, `PYTHONUTF8` and `PYTHONCOERCECLOCALE` environment variables.

## Python Path Configuration

`PyConfig` contains multiple fields for the path configuration:

- Path configuration inputs:
  - `PyConfig.home`
  - `PyConfig.platlibdir`
  - `PyConfig.pathconfig_warnings`
  - `PyConfig.program_name`
  - `PyConfig.pythonpath_env`
  - current working directory: to get absolute paths
  - `PATH` environment variable to get the program full path (from `PyConfig.program_name`)
  - `__PYENV_LAUNCHER__` environment variable
  - (Windows only) Application paths in the registry under “SoftwarePythonPythonCoreX.YPythonPath” of `HKEY_CURRENT_USER` and `HKEY_LOCAL_MACHINE` (where X.Y is the Python version).
- Path configuration output fields:

- `PyConfig.base_exec_prefix`
- `PyConfig.base_executable`
- `PyConfig.base_prefix`
- `PyConfig.exec_prefix`
- `PyConfig.executable`
- `PyConfig.module_search_paths_set,`  
`PyConfig.module_search_paths`
- `PyConfig.prefix`

If at least one “output field” is not set, Python calculates the path configuration to fill unset fields. If `module_search_paths_set` is equal to 0, `module_search_paths` is overridden and `module_search_paths_set` is set to 1.

It is possible to completely ignore the function calculating the default path configuration by setting explicitly all path configuration output fields listed above. A string is considered as set even if it is non-empty. `module_search_paths` is considered as set if `module_search_paths_set` is set to 1. In this case, `module_search_paths` will be used without modification.

Set `pathconfig_warnings` to 0 to suppress warnings when calculating the path configuration (Unix only, Windows does not log any warning).

If `base_prefix` or `base_exec_prefix` fields are not set, they inherit their value from `prefix` and `exec_prefix` respectively.

`Py_RunMain()` and `Py_Main()` modify `sys.path`:

- If `run_filename` is set and is a directory which contains a `__main__.py` script, prepend `run_filename` to `sys.path`.
- If `isolated` is zero:
  - If `run_module` is set, prepend the current directory to `sys.path`. Do nothing if the current directory cannot be read.
  - If `run_filename` is set, prepend the directory of the filename to `sys.path`.
  - Otherwise, prepend an empty string to `sys.path`.

If `site_import` is non-zero, `sys.path` can be modified by the `site` module. If `user_site_directory` is non-zero and the user's site-package directory exists, the `site` module appends the user's site-package directory to `sys.path`.

The following configuration files are used by the path configuration:

- `pyvenv.cfg`
- `._pth` file (ex: `python._pth`)
- `pybuilddir.txt` (Unix only)

If a `._pth` file is present:

- Set `isolated` to 1.
- Set `use_environment` to 0.
- Set `site_import` to 0.
- Set `safe_path` to 1.

The `__PYENVN__LAUNCHER__` environment variable is used to set `PyConfig.base_executable`

## Py\_RunMain()

`int Py_RunMain(void)`

Execute the command (`PyConfig.run_command`), the script (`PyConfig.run_filename`) or the module (`PyConfig.run_module`) specified on the command line or in the configuration.

By default and when if `-i` option is used, run the REPL.

Finally, finalizes Python and returns an exit status that can be passed to the `exit()` function.

See [Python Configuration](#) for an example of customized Python always running in isolated mode using `Py_RunMain()`.

## Py\_GetArgcArgv()

```
void Py_GetArgvArgv(int *argc, wchar_t ***argv)
```

Get the original command line arguments, before Python modified them.

See also [PyConfig.orig\\_argv](#) member.

## Multi-Phase Initialization Private Provisional API

This section is a private provisional API introducing multi-phase initialization, the core feature of [PEP 432](#) [<https://peps.python.org/pep-0432/>]:

- “Core” initialization phase, “bare minimum Python”:
  - Builtin types;
  - Builtin exceptions;
  - Builtin and frozen modules;
  - The `sys` module is only partially initialized (ex: `sys.path` doesn’t exist yet).
- “Main” initialization phase, Python is fully initialized:
  - Install and configure `importlib`;
  - Apply the [Path Configuration](#);
  - Install signal handlers;
  - Finish `sys` module initialization (ex: create `sys.stdout` and `sys.path`);
  - Enable optional features like `faulthandler` and `tracemalloc`;
  - Import the `site` module;
  - etc.

Private provisional API:

- `PyConfig._init_main`: if set to 0, `Py_InitializeFromConfig()` stops at the “Core” initialization phase.

[PyStatus](#) `_Py_InitializeMain(void)`

Move to the “Main” initialization phase, finish the Python initialization.

No module is imported during the “Core” phase and the `importlib` module is not configured: the [Path Configuration](#) is only applied during the “Main” phase. It may allow to customize Python in Python to override or tune the [Path Configuration](#), maybe install a custom `sys.meta_path` importer or an import hook, etc.

It may become possible to calculate the [Path Configuration](#) in Python, after the Core phase and before the Main phase, which is one of the [PEP 432](#) [<https://peps.python.org/pep-0432/>] motivation.

The “Core” phase is not properly defined: what should be and what should not be available at this phase is not specified yet. The API is marked as private and provisional: the API can be modified or even be removed anytime until a proper public API is designed.

Example running Python code between “Core” and “Main” initialization phases:

```
void init_python(void)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);
    config._init_main = 0;

    /* ... customize 'config' configuration ... */

    status = Py_InitializeFromConfig(&config);
    PyConfig_Clear(&config);
    if (PyStatus_Exception(status)) {
        Py_ExitStatusException(status);
    }

    /* Use sys.stderr because sys.stdout is only created
       by _Py_InitializeMain() */
    int res = PyRun_SimpleString(
        "import sys; "
        "print('Run Python code before _Py_InitializeMain',
            "file=sys.stderr)");
```

```
if (res < 0) {
    exit(1);
}

/* ... put more configuration code here ... */

status = _Py_InitializeMain();
if (PyStatus_Exception(status)) {
    Py_ExitStatusException(status);
}
}
```

# Memory Management

## Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the *Python memory manager*. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if they regularly manipulate object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library: `malloc()`, `calloc()`, `realloc()` and `free()`. This will result in mixed calls between the C allocator and the Python

memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
...Do some I/O operation involving buf...
res = PyBytes_FromString(buf);
free(buf); /* malloc'ed */
return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the bytes object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to *inform* the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.

## See also

The [PYTHONMALLOC](#) environment variable can be used to

configure the memory allocators used by Python.

The `PYTHONMALLOCSTATS` environment variable can be used to print statistics of the `pymalloc` memory allocator every time a new `pymalloc` object arena is created, and on shutdown.

## Allocator Domains

All allocating functions belong to one of three different “domains” (see also `PyMemAllocatorDomain`). These domains represent different allocation strategies and are optimized for different purposes. The specific details on how every domain allocates memory or what internal functions each domain calls is considered an implementation detail, but for debugging purposes a simplified table can be found at [here](#). There is no hard requirement to use the memory returned by the allocation functions belonging to a given domain for only the purposes hinted by that domain (although this is the recommended practice). For example, one could use the memory returned by `PyMem_RawMalloc()` for allocating Python objects or the memory returned by `PyObject_Malloc()` for allocating memory for buffers.

The three allocation domains are:

- Raw domain: intended for allocating memory for general-purpose memory buffers where the allocation *must* go to the system allocator or where the allocator can operate without the `GIL`. The memory is requested directly to the system.
- “Mem” domain: intended for allocating memory for Python buffers and general-purpose memory buffers where the allocation must be performed with the `GIL` held. The memory is taken from the Python private heap.
- Object domain: intended for allocating memory belonging to Python objects. The memory is taken from the Python private heap.

When freeing memory previously allocated by the allocating functions belonging to a given domain, the matching specific deallocating functions must be used. For example, `PyMem_Free()` must be used to free memory allocated using `PyMem_Malloc()`.

# Raw Memory Interface

The following function sets are wrappers to the system allocator. These functions are thread-safe, the [GIL](#) does not need to be held.

The [default raw memory allocator](#) uses the following functions:

**malloc()**, **calloc()**, **realloc()** and **free()**; call `malloc(1)` (or `calloc(1, 1)`) when requesting zero bytes.

*New in version 3.4.*

`void *PyMem_RawMalloc(size_t n)`

Allocates *n* bytes and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_RawMalloc(1)` had been called instead. The memory will not have been initialized in any way.

`void *PyMem_RawCalloc(size_t nelem, size_t elsize)`

Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_RawCalloc(1, 1)` had been called instead.

*New in version 3.5.*

`void *PyMem_RawRealloc(void *p, size_t n)`

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyMem_RawMalloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned

pointer is non-NULL.

Unless *p* is NULL, it must have been returned by a previous call to `PyMem_RawMalloc()`, `PyMem_RawRealloc()` or `PyMem_RawCalloc()`.

If the request fails, `PyMem_RawRealloc()` returns NULL and *p* remains a valid pointer to the previous memory area.

`void PyMem_RawFree(void *p)`

Frees the memory block pointed to by *p*, which must have been returned by a previous call to `PyMem_RawMalloc()`, `PyMem_RawRealloc()` or `PyMem_RawCalloc()`.

Otherwise, or if `PyMem_RawFree(p)` has been called before, undefined behavior occurs.

If *p* is NULL, no operation is performed.

## Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

The [default memory allocator](#) uses the [pymalloc memory allocator](#).

### Warning

The [GIL](#) must be held when using these functions.

*Changed in version 3.6:* The default allocator is now `pymalloc` instead of system `malloc()`.

`void *PyMem_Malloc(size_t n)`

*Part of the [Stable ABI](#).*

Allocates *n* bytes and returns a pointer of type `void*` to the allocated memory, or NULL if the request fails.

Requesting zero bytes returns a distinct non-NULL pointer if

possible, as if `PyMem_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

`void *PyMem_Calloc(size_t nelem, size_t elsize)`

*Part of the [Stable ABI](#) since version 3.7.*

Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_Calloc(1, 1)` had been called instead.

*New in version 3.5.*

`void *PyMem_Realloc(void *p, size_t n)`

*Part of the [Stable ABI](#).*

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyMem_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to [PyMem\\_Malloc\(\)](#), [PyMem\\_Realloc\(\)](#) or [PyMem\\_Calloc\(\)](#).

If the request fails, [PyMem\\_Realloc\(\)](#) returns `NULL` and *p* remains a valid pointer to the previous memory area.

`void PyMem_Free(void *p)`

*Part of the [Stable ABI](#).*

Frees the memory block pointed to by *p*, which must have been returned by a previous call to [PyMem\\_Malloc\(\)](#), [PyMem\\_Realloc\(\)](#) or [PyMem\\_Calloc\(\)](#). Otherwise, or if `PyMem_Free(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

The following type-oriented macros are provided for convenience. Note that *TYPE* refers to any C type.

`PyMem_New(TYPE, n)`

Same as `PyMem_Malloc()`, but allocates `(n * sizeof(TYPE))` bytes of memory. Returns a pointer cast to `TYPE*`. The memory will not have been initialized in any way.

`PyMem_Resize(p, TYPE, n)`

Same as `PyMem_Realloc()`, but the memory block is resized to `(n * sizeof(TYPE))` bytes. Returns a pointer cast to `TYPE*`. On return, *p* will be a pointer to the new memory area, or `NULL` in the event of failure.

This is a C preprocessor macro; *p* is always reassigned. Save the original value of *p* to avoid losing memory when handling errors.

`void PyMem_Del(void *p)`

Same as `PyMem_Free()`.

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

- `PyMem_MALLOC(size)`
- `PyMem_NEW(type, size)`
- `PyMem_REALLOC(ptr, size)`
- `PyMem_RESIZE(ptr, type, size)`
- `PyMem_FREE(ptr)`
- `PyMem_DEL(ptr)`

## Object allocators

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

## Note

There is no guarantee that the memory returned by these allocators can be successfully cast to a Python object when intercepting the allocating functions in this domain by the methods described in the [Customize Memory Allocators](#) section.

The [default object allocator](#) uses the [pymalloc memory allocator](#).

## Warning

The [GIL](#) must be held when using these functions.

`void *PyObject_Malloc(size_t n)`

*Part of the [Stable ABI](#).*

Allocates *n* bytes and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyObject_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

`void *PyObject_Calloc(size_t nelem, size_t elsize)`

*Part of the [Stable ABI](#) since version 3.7.*

Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyObject_Calloc(1, 1)` had been called instead.

*New in version 3.5.*

`void *PyObject_Realloc(void *p, size_t n)`

*Part of the [Stable ABI](#).*

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyObject_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to `PyObject_Malloc()`, `PyObject_Realloc()` or `PyObject_Calloc()`.

If the request fails, `PyObject_Realloc()` returns `NULL` and *p* remains a valid pointer to the previous memory area.

`void PyObject_Free(void *p)`

*Part of the [Stable ABI](#).*

Frees the memory block pointed to by *p*, which must have been returned by a previous call to `PyObject_Malloc()`, `PyObject_Realloc()` or `PyObject_Calloc()`.

Otherwise, or if `PyObject_Free(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

## Default Memory Allocators

Default memory allocators:

<code>PyConfig_Malloc</code>
Release build
Debug build
Debug build with debug
Release build, without pymalloc
Debug build, without pymalloc

Legend:

- Name: value for [PYTHONMALLOC](#) environment variable.
- malloc: system allocators from the standard C library, C functions: `malloc()`, `calloc()`, `realloc()` and `free()`.
- pymalloc: [pymalloc memory allocator](#).
- “+ debug”: with [debug hooks on the Python memory allocators](#).
- “Debug build”: [Python build in debug mode](#).

## Customize Memory Allocators

*New in version 3.4.*

type `PyMemAllocatorEx`

Structure used to describe a memory block allocator. The structure has the following fields:

### Members

`user_context` passed as first argument

`allocate_a_memory_block*ctx, size_t size)`

`allocate_a_memory_block*initialized with zeros, size_t  
elsize)`

`allocate or resize a memory blockvoid *ptr, size_t  
new_size)`

`free a memory block*ctx, void *ptr)`

*Changed in version 3.5:* The `PyMemAllocator` structure was renamed to `PyMemAllocatorEx` and a new `calloc` field was added.

type `PyMemAllocatorDomain`

Enum used to identify an allocator domain. Domains:

`PYMEM_DOMAIN_RAW`

Functions:

- `PyMem_RawMalloc()`
- `PyMem_RawRealloc()`
- `PyMem_RawCalloc()`

- `PyMem_RawFree()`

## PYMEM\_DOMAIN\_MEM

Functions:

- `PyMem_Malloc()`,
- `PyMem_Realloc()`
- `PyMem_Calloc()`
- `PyMem_Free()`

## PYMEM\_DOMAIN\_OBJ

Functions:

- `PyObject_Malloc()`
- `PyObject_Realloc()`
- `PyObject_Calloc()`
- `PyObject_Free()`

`void PyMem_GetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)`

Get the memory block allocator of the specified domain.

`void PyMem_SetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)`

Set the memory block allocator of the specified domain.

The new allocator must return a distinct non-NULL pointer when requesting zero bytes.

For the `PYMEM_DOMAIN_RAW` domain, the allocator must be thread-safe: the GIL is not held when the allocator is called.

For the remaining domains, the allocator must also be thread-safe: the allocator may be called in different interpreters that do not share a GIL.

If the new allocator is not a hook (does not call the previous allocator), the `PyMem_SetupDebugHooks()` function must be called to reinstall the debug hooks on top on the new

allocator.

See also [PyPreConfig.allocator](#) and [Preinitialize Python with PyPreConfig](#).

### Warning

[PyMem\\_SetAllocator\(\)](#) does have the following contract:

- It can be called after [Py\\_PreInitialize\(\)](#) and before [Py\\_InitializeFromConfig\(\)](#) to install a custom memory allocator. There are no restrictions over the installed allocator other than the ones imposed by the domain (for instance, the Raw Domain allows the allocator to be called without the GIL held). See [the section on allocator domains](#) for more information.
- If called after Python has finish initializing (after [Py\\_InitializeFromConfig\(\)](#) has been called) the allocator **must** wrap the existing allocator. Substituting the current allocator for some other arbitrary one is **not supported**.

*Changed in version 3.12:* All allocators must be thread-safe.

`void PyMem_SetupDebugHooks(void)`

Setup [debug hooks in the Python memory allocators](#) to detect memory errors.

## Debug hooks on the Python memory allocators

When [Python is built in debug mode](#), the [PyMem\\_SetupDebugHooks\(\)](#) function is called at the [Python preinitialization](#) to setup debug hooks on Python memory allocators to detect memory errors.

The [PYTHONMALLOC](#) environment variable can be used to install

debug hooks on a Python compiled in release mode (ex: PYTHONMALLOC=debug).

The `PyMem_SetupDebugHooks()` function can be used to set debug hooks after calling `PyMem_SetAllocator()`.

These debug hooks fill dynamically allocated memory blocks with special, recognizable bit patterns. Newly allocated memory is filled with the byte `0xCD` (`PYMEM_CLEANBYTE`), freed memory is filled with the byte `0xDD` (`PYMEM_DEADBYTE`). Memory blocks are surrounded by “forbidden bytes” filled with the byte `0xFD` (`PYMEM_FORBIDDENBYTE`). Strings of these bytes are unlikely to be valid addresses, floats, or ASCII strings.

Runtime checks:

- Detect API violations. For example, detect if `PyObject_Free()` is called on a memory block allocated by `PyMem_Malloc()`.
- Detect write before the start of the buffer (buffer underflow).
- Detect write after the end of the buffer (buffer overflow).
- Check that the `GIL` is held when allocator functions of `PYMEM_DOMAIN_OBJ` (ex: `PyObject_Malloc()`) and `PYMEM_DOMAIN_MEM` (ex: `PyMem_Malloc()`) domains are called.

On error, the debug hooks use the `tracemalloc` module to get the traceback where a memory block was allocated. The traceback is only displayed if `tracemalloc` is tracing Python memory allocations and the memory block was traced.

Let  $S = \text{sizeof}(\text{size\_t})$ .  $2 \cdot S$  bytes are added at each end of each block of  $N$  bytes requested. The memory layout is like so, where  $p$  represents the address returned by a malloc-like or realloc-like function ( $p[i:j]$  means the slice of bytes from  $* (p+i)$  inclusive up to  $* (p+j)$  exclusive; note that the treatment of negative indices differs from a Python slice):

$p[-2 \cdot S:-S]$

Number of bytes originally asked for. This is a `size_t`, big-endian (easier to read in a memory dump).

`p[-S]`

API identifier (ASCII character):

- 'r' for `PYMEM_DOMAIN_RAW`.
- 'm' for `PYMEM_DOMAIN_MEM`.
- 'o' for `PYMEM_DOMAIN_OBJ`.

`p[-S+1:0]`

Copies of `PYMEM_FORBIDDENBYTE`. Used to catch under-writes and reads.

`p[0:N]`

The requested memory, filled with copies of `PYMEM_CLEANBYTE`, used to catch reference to uninitialized memory. When a `realloc`-like function is called requesting a larger memory block, the new excess bytes are also filled with `PYMEM_CLEANBYTE`. When a `free`-like function is called, these are overwritten with `PYMEM_DEADBYTE`, to catch reference to freed memory. When a `realloc`-like function is called requesting a smaller memory block, the excess old bytes are also filled with `PYMEM_DEADBYTE`.

`p[N:N+S]`

Copies of `PYMEM_FORBIDDENBYTE`. Used to catch over-writes and reads.

`p[N+S:N+2*S]`

Only used if the `PYMEM_DEBUG_SERIALNO` macro is defined (not defined by default).

A serial number, incremented by 1 on each call to a `malloc`-like or `realloc`-like function. Big-endian `size_t`. If “bad memory” is detected later, the serial number gives an excellent way to set a breakpoint on the next run, to capture the instant at which this block was passed out. The static function `bumpserialno()` in `obmalloc.c` is the only place the serial number is incremented, and exists so you can set such a breakpoint easily.

A `realloc`-like or `free`-like function first checks that the

PYMEM\_FORBIDDENBYTE bytes at each end are intact. If they've been altered, diagnostic output is written to stderr, and the program is aborted via `Py_FatalError()`. The other main failure mode is provoking a memory error when a program reads up one of the special bit patterns and tries to use it as an address. If you get in a debugger then and look at the object, you're likely to see that it's entirely filled with PYMEM\_DEADBYTE (meaning freed memory is getting used) or PYMEM\_CLEANBYTE (meaning uninitialized memory is getting used).

*Changed in version 3.6:* The `PyMem_SetupDebugHooks()` function now also works on Python compiled in release mode. On error, the debug hooks now use `tracemalloc` to get the traceback where a memory block was allocated. The debug hooks now also check if the GIL is held when functions of `PYMEM_DOMAIN_OBJ` and `PYMEM_DOMAIN_MEM` domains are called.

*Changed in version 3.8:* Byte patterns `0xCB` (PYMEM\_CLEANBYTE), `0xDB` (PYMEM\_DEADBYTE) and `0xFB` (PYMEM\_FORBIDDENBYTE) have been replaced with `0xCD`, `0xDD` and `0xFD` to use the same values than Windows CRT debug `malloc()` and `free()`.

## The pymalloc allocator

Python has a *pymalloc* allocator optimized for small objects (smaller or equal to 512 bytes) with a short lifetime. It uses memory mappings called “arenas” with a fixed size of 256 KiB. It falls back to `PyMem_RawMalloc()` and `PyMem_RawRealloc()` for allocations larger than 512 bytes.

*pymalloc* is the *default allocator* of the `PYMEM_DOMAIN_MEM` (ex: `PyMem_Malloc()`) and `PYMEM_DOMAIN_OBJ` (ex: `PyObject_Malloc()`) domains.

The arena allocator uses the following functions:

- `VirtualAlloc()` and `VirtualFree()` on Windows,
- `mmap()` and `munmap()` if available,
- `malloc()` and `free()` otherwise.

This allocator is disabled if Python is configured with the `--without-pymalloc` option. It can also be disabled at runtime using the `PYTHONMALLOC` environment variable (ex: `PYTHONMALLOC=malloc`).

## Customize pymalloc Arena Allocator

*New in version 3.4.*

type PyObjectArenaAllocator

Structure used to describe an arena allocator. The structure has three fields:

### Mechanism

---

user context passed as first argument

---

allocate an arena of size bytes `size_t size)`

---

free an arena `(void *ctx, void *ptr, size_t size)`

---

`void PyObject_GetArenaAllocator(PyObjectArenaAllocator  
*allocator)`

Get the arena allocator.

`void PyObject_SetArenaAllocator(PyObjectArenaAllocator  
*allocator)`

Set the arena allocator.

## tracemalloc C API

*New in version 3.7.*

`int PyTraceMalloc_Track(unsigned int domain, uintptr_t ptr, size_t  
size)`

Track an allocated memory block in the `tracemalloc` module.

Return 0 on success, return -1 on error (failed to allocate memory to store the trace). Return -2 if tracemalloc is

disabled.

If memory block is already tracked, update the existing trace.

`int PyTraceMalloc_Untrack(unsigned int domain, uintptr_t ptr)`

Untrack an allocated memory block in the `tracemalloc` module. Do nothing if the block was not tracked.

Return `-2` if `tracemalloc` is disabled, otherwise return `0`.

## Examples

Here is the example from section [Overview](#), rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always

manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as *fatal* because it mixes two different allocators operating on different heaps.

```
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3); /* Wrong -- should be PyMem_Free() */
free(buf2);      /* Right -- allocated via malloc() */
free(buf1);      /* Fatal -- should be PyMem_Del() */
```

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with `PyObject_New`, `PyObject_NewVar` and `PyObject_Del()`.

These will be explained in the next chapter on defining and implementing new object types in C.

# Object Implementation Support

# Allocating Objects on the Heap

`PyObject *``PyObject_New(PyTypeObject *type)`

*Return value:* New reference.

`PyVarObject *``PyObject_NewVar(PyTypeObject *type, Py_ssize_t size)`

*Return value:* New reference.

`PyObject *``PyObject_Init(PyObject *op, PyTypeObject *type)`

*Return value:* Borrowed reference. Part of the [Stable ABI](#).

Initialize a newly allocated object `op` with its type and initial reference. Returns the initialized object. If `type` indicates that the object participates in the cyclic garbage detector, it is added to the detector's set of observed objects. Other fields of the object are not affected.

`PyVarObject *``PyObject_InitVar(PyVarObject *op, PyTypeObject *type, Py_ssize_t size)`

*Return value:* Borrowed reference. Part of the [Stable ABI](#).

This does everything `PyObject_Init()` does, and also initializes the length information for a variable-size object.

`PyObject_New(TYPE, typeobj)`

Allocate a new Python object using the C structure type `TYPE` and the Python type object `typeobj` (`PyTypeObject *`). Fields not defined by the Python object header are not initialized. The caller will own the only reference to the object (i.e. its reference count will be one). The size of the memory allocation is determined from the `tp_basicsize` field of the type object.

**PyObject\_NewVar**(TYPE, typeobj, size)

Allocate a new Python object using the C structure type *TYPE* and the Python type object *typeobj* (`PyTypeObject*`). Fields not defined by the Python object header are not initialized. The allocated memory allows for the *TYPE* structure plus *size* (`Py_ssize_t`) fields of the size given by the `tp_itemsize` field of *typeobj*. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

**void PyObject\_Del**(void \*op)

Releases memory allocated to an object using `PyObject_New` or `PyObject_NewVar`. This is normally called from the `tp_dealloc` handler specified in the object's type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

**PyObject\_Py\_NoneStruct**

Object which is visible in Python as `None`. This should only be accessed using the `Py_None` macro, which evaluates to a pointer to this object.

**See also**

**`PyModule_Create()`**

To allocate and create extension modules.

# Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

## Base object types and macros

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the `PyObject` and `PyVarObject` types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects. Additional macros can be found under [reference counting](#).

type `PyObject`

*Part of the [Limited API](#). (Only some members are part of the stable ABI.)*

All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal “release” build, it contains only the object's reference count and a pointer to the corresponding type object. Nothing is actually declared to be a `PyObject`, but every pointer to a Python object can be cast to a `PyObject*`. Access to the members must be done by using the macros `Py_REFCNT` and `Py_TYPE`.

type `PyVarObject`

*Part of the [Limited API](#). (Only some members are part of the stable ABI.)*

This is an extension of `PyObject` that adds the `ob_size` field. This is only used for objects that have some notion of *length*. This type does not often appear in the Python/C API. Access to the members must be done by using the macros `Py_REFCNT`, `Py_TYPE`, and `Py_SIZE`.

## PyObject\_HEAD

This is a macro used when declaring new types which represent objects without a varying length. The PyObject\_HEAD macro expands to:

```
PyObject ob_base;
```

See documentation of [PyObject](#) above.

## PyObject\_VAR\_HEAD

This is a macro used when declaring new types which represent objects with a length that varies from instance to instance. The PyObject\_VAR\_HEAD macro expands to:

```
PyVarObject ob_base;
```

See documentation of [PyVarObject](#) above.

## int Py\_Is(PyObject \*x, PyObject \*y)

*Part of the [Stable ABI](#) since version 3.10.*

Test if the `x` object is the `y` object, the same as `x is y` in Python.

*New in version 3.10.*

## int Py\_IsNone(PyObject \*x)

*Part of the [Stable ABI](#) since version 3.10.*

Test if an object is the `None` singleton, the same as `x is None` in Python.

*New in version 3.10.*

## int Py\_IsTrue(PyObject \*x)

*Part of the [Stable ABI](#) since version 3.10.*

Test if an object is the `True` singleton, the same as `x is True` in Python.

*New in version 3.10.*

`int Py_IsFalse(PyObject *x)`

*Part of the [Stable ABI](#) since version 3.10.*

Test if an object is the `False` singleton, the same as `x is False` in Python.

*New in version 3.10.*

`PyTypeObject *Py_TYPE(PyObject *o)`

Get the type of the Python object `o`.

Return a [borrowed reference](#).

Use the [Py\\_SET\\_TYPE\(\)](#) function to set an object type.

*Changed in version 3.11:* [Py\\_TYPE\(\)](#) is changed to an inline static function. The parameter type is no longer `const PyObject*`.

`int Py_IS_TYPE(PyObject *o, PyTypeObject *type)`

Return non-zero if the object `o` type is `type`. Return zero otherwise. Equivalent to: `Py_TYPE(o) == type`.

*New in version 3.9.*

`void Py_SET_TYPE(PyObject *o, PyTypeObject *type)`

Set the object `o` type to `type`.

*New in version 3.9.*

`Py_ssize_t Py_SIZE(PyVarObject *o)`

Get the size of the Python object `o`.

Use the [Py\\_SET\\_SIZE\(\)](#) function to set an object size.

*Changed in version 3.11:* [Py\\_SIZE\(\)](#) is changed to an inline static function. The parameter type is no longer `const PyVarObject*`.

```
void Py_SET_SIZE(PyVarObject *o, Py_ssize_t size)
```

Set the object *o* size to *size*.

*New in version 3.9.*

```
PyObject_HEAD_INIT(type)
```

This is a macro which expands to initialization values for a new **PyObject** type. This macro expands to:

```
_PyObject_EXTRA_INIT  
1, type,
```

```
PyVarObject_HEAD_INIT(type, size)
```

This is a macro which expands to initialization values for a new **PyVarObject** type, including the **ob\_size** field. This macro expands to:

```
_PyObject_EXTRA_INIT  
1, type, size,
```

## Implementing functions and methods

type PyCFunction

*Part of the [Stable ABI](#).*

Type of the functions used to implement most Python callables in C. Functions of this type take two **PyObject\*** parameters and return one such value. If the return value is `NULL`, an exception shall have been set. If not `NULL`, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

The function signature is:

```
PyObject *PyCFunction(PyObject *self,  
                      PyObject *args);
```

type PyCFunctionWithKeywords

Part of the *Stable ABI*.

Type of the functions used to implement Python callables in C with signature [METH\\_VARARGS](#) | [METH\\_KEYWORDS](#). The function signature is:

```
PyObject *PyCFunctionWithKeywords(PyObject *self,  
                                   PyObject *args,  
                                   PyObject *kwargs)
```

type `_PyCFunctionFast`

Type of the functions used to implement Python callables in C with signature [METH\\_FASTCALL](#). The function signature is:

```
PyObject *_PyCFunctionFast(PyObject *self,  
                           PyObject *const *args,  
                           Py_ssize_t nargs);
```

type `_PyCFunctionFastWithKeywords`

Type of the functions used to implement Python callables in C with signature [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#). The function signature is:

```
PyObject *_PyCFunctionFastWithKeywords(PyObject *self,  
  PyObject *const *args,  
  Py_ssize_t nargs,  
  PyObject *kwargs)
```

type `PyCMethod`

Type of the functions used to implement Python callables in C with signature [METH\\_METHOD](#) | [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#). The function signature is:

```
PyObject *PyCMethod(PyObject *self,  
                    PyTypeObject *defining_class,  
                    PyObject *const *args,  
                    Py_ssize_t nargs,  
                    PyObject *kwnames)
```

*New in version 3.9.*

type PyMethodDef

Part of the *Stable ABI* (including all members).

Structure used to describe a method of an extension type.

This structure has four fields:

const char \*ml\_name

Name of the method.

PyCFunction ml\_meth

Pointer to the C implementation.

int ml\_flags

Flags bits indicating how the call should be constructed.

const char \*ml\_doc

Points to the contents of the docstring.

The `ml_meth` is a C function pointer. The functions may be of different types, but they always return `PyObject*`. If the function is not of the `PyCFunction`, the compiler will require a cast in the method table. Even though `PyCFunction` defines the first parameter as `PyObject*`, it is common that the method implementation uses the specific C type of the *self* object.

The `ml_flags` field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention.

There are these calling conventions:

#### METH\_VARARGS

This is the typical calling convention, where the methods have the type `PyCFunction`. The function expects two `PyObject*` values. The first one is the *self* object for methods; for module functions, it is the module object. The second parameter (often called *args*) is a tuple object representing all arguments. This parameter is typically processed using `PyArg_ParseTuple()` or `PyArg_UnpackTuple()`.

## METH\_KEYWORDS

Can only be used in certain combinations with other flags:

[METH\\_VARARGS](#) | [METH\\_KEYWORDS](#), [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#) and [METH\\_METHOD](#) | [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#).

## [METH\\_VARARGS](#) | [METH\\_KEYWORDS](#)

Methods with these flags must be of type

[PyCFunctionWithKeywords](#). The function expects three parameters: *self*, *args*, *kwargs* where *kwargs* is a dictionary of all the keyword arguments or possibly `NULL` if there are no keyword arguments. The parameters are typically processed using [PyArg\\_ParseTupleAndKeywords\(\)](#).

## METH\_FASTCALL

Fast calling convention supporting only positional arguments. The methods have the type [\\_PyCFunctionFast](#). The first parameter is *self*, the second parameter is a C array of [PyObject\\*](#) values indicating the arguments and the third parameter is the number of arguments (the length of the array).

*New in version 3.7.*

*Changed in version 3.10:* `METH_FASTCALL` is now part of the [stable ABI](#).

## [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#)

Extension of [METH\\_FASTCALL](#) supporting also keyword arguments, with methods of type

[\\_PyCFunctionFastWithKeywords](#). Keyword arguments are passed the same way as in the [vectorcall protocol](#): there is an additional fourth [PyObject\\*](#) parameter which is a tuple representing the names of the keyword arguments (which are guaranteed to be strings) or possibly `NULL` if there are no keywords. The values of the keyword arguments are stored in the *args* array, after the positional arguments.

*New in version 3.7.*

## METH\_METHOD

Can only be used in the combination with other flags:  
[METH\\_METHOD](#) | [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#).

## [METH\\_METHOD](#) | [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#)

Extension of [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#) supporting the *defining class*, that is, the class that contains the method in question. The defining class might be a superclass of `Py_TYPE(self)`.

The method needs to be of type [PyCMethod](#), the same as for [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#) with `defining_class` argument added after `self`.

*New in version 3.9.*

## METH\_NOARGS

Methods without parameters don't need to check whether arguments are given if they are listed with the [METH\\_NOARGS](#) flag. They need to be of type [PyCFunction](#). The first parameter is typically named *self* and will hold a reference to the module or object instance. In all cases the second parameter will be `NULL`.

The function must have 2 parameters. Since the second parameter is unused, [Py\\_UNUSED](#) can be used to prevent a compiler warning.

## METH\_O

Methods with a single object argument can be listed with the [METH\\_O](#) flag, instead of invoking [PyArg\\_ParseTuple\(\)](#) with a "O" argument. They have the type [PyCFunction](#), with the *self* parameter, and a [PyObject\\*](#) parameter representing the single argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

## METH\_CLASS

The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create *class methods*, similar to what is created when using the `classmethod()` built-in function.

## METH\_STATIC

The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the `staticmethod()` built-in function.

One other constant controls whether a method is loaded in place of another definition with the same method name.

## METH\_COEXIST

The method will be loaded in place of existing definitions. Without `METH_COEXIST`, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a `sq_contains` slot, for example, would generate a wrapped method named `__contains__()` and preclude the loading of a corresponding `PyCFunction` with the same name. With the flag defined, the `PyCFunction` will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to `PyCFunctions` are optimized more than wrapper object calls.

# Accessing attributes of extension types

type `PyMemberDef`

Part of the *Stable ABI* (including all members).

Structure which describes an attribute of a type which corresponds to a C struct member. Its fields are, in order:

`const char *name`

Name of the member. A `NULL` value marks the end of a `PyMemberDef[]` array.

The string should be static, no copy is made of it.

#### `Py_ssize_t` offset

The offset in bytes that the member is located on the type's object struct.

#### `int` type

The type of the member in the C struct. See [Member types](#) for the possible values.

#### `int` flags

Zero or more of the [Member flags](#), combined using bitwise OR.

#### `const char *`doc

The docstring, or NULL. The string should be static, no copy is made of it. Typically, it is defined using [PyDoc\\_STR](#).

By default (when [flags](#) is 0), members allow both read and write access. Use the [Py\\_READONLY](#) flag for read-only access. Certain types, like [Py\\_T\\_STRING](#), imply [Py\\_READONLY](#). Only [Py\\_T\\_OBJECT\\_EX](#) (and legacy [T\\_OBJECT](#)) members can be deleted.

For heap-allocated types (created using [PyType\\_FromSpec\(\)](#) or similar), `PyMemberDef` may contain a definition for the special member `"__vectorcalloffset__"`, corresponding to [tp\\_vectorcall\\_offset](#) in type objects. These must be defined with `Py_T_PYSSIZET` and `Py_READONLY`, for example:

```
static PyMemberDef spam_type_members[] = {
    {"__vectorcalloffset__", Py_T_PYSSIZET,
     offsetof(Spam_object, vectorcall), Py_READONLY,
     {NULL}} /* Sentinel */
};
```

(You may need to `#include <stddef.h>` for `offsetof()`.)

The legacy offsets `tp_dictoffset` and `tp_weaklistoffset` can be defined similarly using `"__dictoffset__"` and `"__weaklistoffset__"` members, but extensions are strongly encouraged to use `Py_TPFLAGS_MANAGED_DICT` and `Py_TPFLAGS_MANAGED_WEAKREF` instead.

*Changed in version 3.12:* `PyMemberDef` is always available. Previously, it required including `"structmember.h"`.

`PyObject *``PyMember_GetOne`(`const char *``obj_addr`, `struct PyMemberDef *``m`)

*Part of the [Stable ABI](#).*

Get an attribute belonging to the object at address `obj_addr`. The attribute is described by `PyMemberDef m`. Returns `NULL` on error.

*Changed in version 3.12:* `PyMember_GetOne` is always available. Previously, it required including `"structmember.h"`.

`int` `PyMember_SetOne`(`char *``obj_addr`, `struct PyMemberDef *``m`, `PyObject *``o`)

*Part of the [Stable ABI](#).*

Set an attribute belonging to the object at address `obj_addr` to object `o`. The attribute to set is described by `PyMemberDef m`. Returns `0` if successful and a negative value on failure.

*Changed in version 3.12:* `PyMember_SetOne` is always available. Previously, it required including `"structmember.h"`.

## Member flags

The following flags can be used with `PyMemberDef.flags`:

## Py\_READONLY

Not writable.

## Py\_AUDIT\_READ

Emit an `object.__getattr__` [audit event](#) before reading.

## Py\_RELATIVE\_OFFSET

Indicates that the [offset](#) of this `PyMemberDef` entry indicates an offset from the subclass-specific data, rather than from `PyObject`.

Can only be used as part of [Py\\_tp\\_members](#) slot when creating a class using negative [basicsize](#). It is mandatory in that case.

This flag is only used in `PyTypeSlot`. When setting [tp\\_members](#) during class creation, Python clears it and sets [PyMemberDef.offset](#) to the offset from the `PyObject` struct.

*Changed in version 3.10:* The `RESTRICTED`, `READ_RESTRICTED` and `WRITE_RESTRICTED` macros available with `#include "structmember.h"` are deprecated. `READ_RESTRICTED` and `RESTRICTED` are equivalent to [Py\\_AUDIT\\_READ](#); `WRITE_RESTRICTED` does nothing.

*Changed in version 3.12:* The `READONLY` macro was renamed to [Py\\_READONLY](#). The `PY_AUDIT_READ` macro was renamed with the `Py_` prefix. The new names are now always available. Previously, these required `#include "structmember.h"`. The header is still available and it provides the old names.

## Member types

[PyMemberDef.type](#) can be one of the following macros corresponding to various C types. When the member is accessed in Python, it will be converted to the equivalent Python type. When it is set from Python, it will be converted back to the C type. If that is not possible, an exception such as [TypeError](#) or [ValueError](#) is

raised.

Unless marked (D), attributes defined this way cannot be deleted using e.g. `del` or `delattr()`.

### **Member type**

`Py_t_BYTE`

`Py_t_SHORT`

`Py_t_INT`

`Py_t_LONG`

`Py_t_LONGLONG`

`Py_t_HALF`

`Py_t_INT_t`

`Py_t_USHORT`

`Py_t_ULONG`

`Py_t_ULONG_LONG`

`Py_t_PYSIZE_T`

`Py_t_FLOAT`

`Py_t_DOUBLE`

`Py_t_BOOL` (often as 0 or 1)

`Py_t_STRING*`

`Py_t_STRING_INPLACE`

`Py_t_CHAR`

`Py_t_OBJ_T_EX`

(\*): Zero-terminated, UTF8-encoded C string. With **Py\_t\_STRING** the C representation is a pointer; with **Py\_t\_STRING\_INLINE** the string is stored directly in the structure.

(\*\*): String of length 1. Only ASCII is accepted.

(RO): Implies **Py\_READONLY**.

(D): Can be deleted, in which case the pointer is set to NULL. Reading a NULL pointer raises **AttributeError**.

*New in version 3.12:* In previous versions, the macros were only available with `#include "structmember.h"` and were named without the `Py_` prefix (e.g. as `T_INT`). The header is still

available and contains the old names, along with the following deprecated types:

## T\_OBJECT

Like `Py_T_OBJECT_EX`, but `NULL` is converted to `None`. This results in surprising behavior in Python: deleting the attribute effectively sets it to `None`.

## T\_NONE

Always `None`. Must be used with `Py_READONLY`.

## Defining Getters and Setters

type `PyGetSetDef`

*Part of the [Stable ABI](#) (including all members).*

Structure to define property-like access for a type. See also description of the `PyTypeObject.tp_getset` slot.

`const char *name`

attribute name

getter `get`

C function to get the attribute.

setter `set`

Optional C function to set or delete the attribute, if omitted the attribute is readonly.

`const char *doc`

optional docstring

`void *closure`

Optional function pointer, providing additional data for getter and setter.

The `get` function takes one `PyObject*` parameter (the instance) and a function pointer (the associated `closure`):

```
typedef PyObject *(*getter)(PyObject *, void *);
```

It should return a new reference on success or `NULL` with a set exception on failure.

set functions take two `PyObject*` parameters (the instance and the value to be set) and a function pointer (the associated closure):

```
typedef int (*setter)(PyObject *, PyObject *, void
```

In case the attribute should be deleted the second parameter is `NULL`. Should return `0` on success or `-1` with a set exception on failure.

# Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the `PyTypeObject` structure. Type objects can be handled using any of the `PyObject_*` or `PyType_*` functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

In addition to the following quick reference, the [Examples](#) section provides at-a-glance insight into the meaning and use of `PyTypeObject`.

1

**()**: A slot name in parentheses indicates it is (effectively) deprecated.

**<>**: Names in angle brackets should be initially set to `NULL` and treated as read-only.

**[]**: Names in square brackets are for internal use only.

**<R>** (as a prefix) means the field is required (must be non-`NULL`).

2

Columns:

**"O"**: set on `PyBaseObject_Type`

**"T"**: set on `PyType_Type`

**"D"**: default (if slot is set to `NULL`)

X - `PyType_Ready` sets this value if it is `NULL`

~ - `PyType_Ready` always sets this value (it should be)

? - `PyType_Ready` may set this value depending on other

Also see the inheritance column ("I").

**"I"**: inheritance

X - type slot is inherited via `*PyType_Ready*` if def.

% - the slots of the sub-struct are inherited individually

G - inherited, but only in combination with other slots

? - it's complicated; see the slot's description

Note that some slots are effectively inherited through the normal attribute lookup chain.

```

## PyObject Slots

The type object structure extends the [PyVarObject](#) structure. The [ob\\_size](#) field is used for dynamic types (created by [type\\_new\(\)](#), usually called from a class statement). Note that [PyType\\_Type](#) (the metatype) initializes [tp\\_itemsize](#), which means that its instances (i.e. type objects) *must* have the [ob\\_size](#) field.

[Py\\_ssize\\_t PyObject.ob\\_refcnt](#)

*Part of the [Stable ABI](#).*

This is the type object's reference count, initialized to 1 by the `PyObject_HEAD_INIT` macro. Note that for [statically allocated type objects](#), the type's instances (objects whose [ob\\_type](#) points back to the type) do *not* count as references. But for [dynamically allocated type objects](#), the instances *do* count as references.

### Inheritance:

This field is not inherited by subtypes.

[PyTypeObject \\*PyObject.ob\\_type](#)

Part of the *Stable ABI*.

This is the type's type, in other words its metatype. It is initialized by the argument to the `PyObject_HEAD_INIT` macro, and its value should normally be `&PyType_Type`. However, for dynamically loadable extension modules that must be usable on Windows (at least), the compiler complains that this is not a valid initializer. Therefore, the convention is to pass `NULL` to the `PyObject_HEAD_INIT` macro and to initialize this field explicitly at the start of the module's initialization function, before doing anything else. This is typically done like this:

```
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. `PyType_Ready()` checks if `ob_type` is `NULL`, and if so, initializes it to the `ob_type` field of the base class. `PyType_Ready()` will not change this field if it is non-zero.

### Inheritance:

This field is inherited by subtypes.

`PyObject *PyObject._ob_next`

`PyObject *PyObject._ob_prev`

These fields are only present when the macro `Py_TRACE_REFS` is defined (see the `configure --with-trace-refs` option).

Their initialization to `NULL` is taken care of by the `PyObject_HEAD_INIT` macro. For [statically allocated objects](#), these fields always remain `NULL`. For [dynamically allocated objects](#), these two fields are used to link the object into a doubly linked list of *all* live objects on the heap.

This could be used for various debugging purposes; currently the only uses are the `sys.getobjects()` function and to print the objects that are still alive at the end of a run when the environment variable `PYTHONDUMPREFS` is set.

### Inheritance:

These fields are not inherited by subtypes.

## PyVarObject Slots

`Py_ssize_t PyVarObject.ob_size`

Part of the *Stable ABI*.

For [statically allocated type objects](#), this should be initialized to zero. For [dynamically allocated type objects](#), this field has a special internal meaning.

### Inheritance:

This field is not inherited by subtypes.

## PyTypeObject Slots

Each slot has a section describing inheritance. If `PyType_Ready()` may set a value when the field is set to `NULL` then there will also be a “Default” section. (Note that many fields set on `PyBaseObject_Type` and `PyType_Type` effectively act as defaults.)

`const char *PyTypeObject.tp_name`

Pointer to a NUL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named `T` defined in module `M` in subpackage `Q` in package `P` should have the `tp_name` initializer `"P.Q.M.T"`.

For [dynamically allocated type objects](#), this should just be the type name, and the module name explicitly stored in the type dict as the value for key `'__module__'`.

For [statically allocated type objects](#), the `tp_name` field should contain a dot. Everything before the last dot is made

accessible as the `__module__` attribute, and everything after the last dot is made accessible as the `__name__` attribute.

If no dot is present, the entire `tp_name` field is made accessible as the `__name__` attribute, and the `__module__` attribute is undefined (unless explicitly set in the dictionary, as explained above). This means your type will be impossible to pickle. Additionally, it will not be listed in module documentations created with pydoc.

This field must not be `NULL`. It is the only required field in `PyTypeObject()` (other than potentially `tp_itemsize`).

### Inheritance:

This field is not inherited by subtypes.

`Py_ssize_t PyTypeObject.tp_basicsize`

`Py_ssize_t PyTypeObject.tp_itemsize`

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero `tp_itemsize` field, types with variable-length instances have a non-zero `tp_itemsize` field. For a type with fixed-length instances, all instances have the same size, given in `tp_basicsize`.

For a type with variable-length instances, the instances must have an `ob_size` field, and the instance size is `tp_basicsize` plus N times `tp_itemsize`, where N is the “length” of the object. The value of N is typically stored in the instance’s `ob_size` field. There are exceptions: for example, ints use a negative `ob_size` to indicate a negative number, and N is `abs(ob_size)` there. Also, the presence of an `ob_size` field in the instance layout doesn’t mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful `ob_size` field).

The basic size includes the fields in the instance declared by

the macro `PyObject_HEAD` or `PyObject_VAR_HEAD` (whichever is used to declare the instance struct) and this in turn includes the `_ob_prev` and `_ob_next` fields if they are present. This means that the only correct way to get an initializer for the `tp_basicsize` is to use the `sizeof` operator on the struct used to declare the instance layout. The basic size does not include the GC header size.

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of `tp_basicsize`. Example: suppose a type implements an array of `double`. `tp_itemsize` is `sizeof(double)`. It is the programmer's responsibility that `tp_basicsize` is a multiple of `sizeof(double)` (assuming this is the alignment requirement for `double`).

For any type with variable-length instances, this field must not be `NULL`.

### Inheritance:

These fields are inherited separately by subtypes. If the base type has a non-zero `tp_itemsize`, it is generally not safe to set `tp_itemsize` to a different non-zero value in a subtype (though this depends on the implementation of the base type).

### destructor `PyTypeObject.tp_dealloc`

A pointer to the instance destructor function. This function must be defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons `None` and `Ellipsis`). The function signature is:

```
void tp_dealloc(PyObject *self);
```

The destructor function is called by the `Py_DECREF()` and `Py_XDECREF()` macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function

corresponding to the allocation function used to allocate the buffer), and call the type's `tp_free` function. If the type is not subtypable (doesn't have the `Py_TPFLAGS_BASETYPE` flag bit set), it is permissible to call the object deallocator directly instead of via `tp_free`. The object deallocator should be the one used to allocate the instance; this is normally `PyObject_Del()` if the instance was allocated using `PyObject_New` or `PyObject_NewVar`, or `PyObject_GC_Del()` if the instance was allocated using `PyObject_GC_New` or `PyObject_GC_NewVar`.

If the type supports garbage collection (has the `Py_TPFLAGS_HAVE_GC` flag bit set), the destructor should call `PyObject_GC_UnTrack()` before clearing any member fields.

```
static void foo_dealloc(foo_object *self) {
    PyObject_GC_UnTrack(self);
    Py_CLEAR(self->ref);
    Py_TYPE(self)->tp_free((PyObject *)self);
}
```

Finally, if the type is heap allocated (`Py_TPFLAGS_HEAPTYPE`), the deallocator should release the owned reference to its type object (via `Py_DECREF()`) after calling the type deallocator. In order to avoid dangling pointers, the recommended way to achieve this is:

```
static void foo_dealloc(foo_object *self) {
    PyTypeObject *tp = Py_TYPE(self);
    // free references and buffers here
    tp->tp_free(self);
    Py_DECREF(tp);
}
```

## Inheritance:

This field is inherited by subtypes.

`Py_ssize_t PyObject.tp_vectorcall_offset`

An optional offset to a per-instance function that implements calling the object using the [vectorcall protocol](#), a more efficient alternative of the simpler [tp\\_call](#).

This field is only used if the flag [Py\\_TPFLAGS\\_HAVE\\_VECTORCALL](#) is set. If so, this must be a positive integer containing the offset in the instance of a [vectorcallfunc](#) pointer.

The *vectorcallfunc* pointer may be `NULL`, in which case the instance behaves as if [Py\\_TPFLAGS\\_HAVE\\_VECTORCALL](#) was not set: calling the instance falls back to [tp\\_call](#).

Any class that sets `Py_TPFLAGS_HAVE_VECTORCALL` must also set [tp\\_call](#) and make sure its behaviour is consistent with the *vectorcallfunc* function. This can be done by setting *tp\_call* to [PyVectorcall\\_Call\(\)](#).

*Changed in version 3.8:* Before version 3.8, this slot was named `tp_print`. In Python 2.x, it was used for printing to a file. In Python 3.0 to 3.7, it was unused.

*Changed in version 3.12:* Before version 3.12, it was not recommended for [mutable heap types](#) to implement the vectorcall protocol. When a user sets `__call__` in Python code, only *tp\_call* is updated, likely making it inconsistent with the vectorcall function. Since 3.12, setting `__call__` will disable vectorcall optimization by clearing the [Py\\_TPFLAGS\\_HAVE\\_VECTORCALL](#) flag.

## Inheritance:

This field is always inherited. However, the [Py\\_TPFLAGS\\_HAVE\\_VECTORCALL](#) flag is not always inherited. If it's not set, then the subclass won't use [vectorcall](#), except when [PyVectorcall\\_Call\(\)](#) is explicitly called.

[getattrfunc](#) [PyTypeObject](#).[tp\\_getattr](#)

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_getattro` function, but taking a C string instead of a Python string object to give the attribute name.

### Inheritance:

Group: `tp_getattr`, `tp_getattro`

This field is inherited by subtypes together with `tp_getattro`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

### `setattrfunc PyTypeObject.tp_setattr`

An optional pointer to the function for setting and deleting attributes.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_setattro` function, but taking a C string instead of a Python string object to give the attribute name.

### Inheritance:

Group: `tp_setattr`, `tp_setattro`

This field is inherited by subtypes together with `tp_setattro`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

### `PyAsyncMethods *PyTypeObject.tp_as_async`

Pointer to an additional structure that contains fields relevant only to objects which implement `awaitable` and `asynchronous iterator` protocols at the C-level. See [Async Object Structures](#) for details.

*New in version 3.5:* Formerly known as `tp_compare` and `tp_reserved`.

## Inheritance:

The `tp_as_async` field is not inherited, but the contained fields are inherited individually.

`reprfunc PyTypeObject.tp_repr`

An optional pointer to a function that implements the built-in function `repr()`.

The signature is the same as for `PyObject_Repr()`:

```
PyObject *tp_repr(PyObject *self);
```

The function must return a string or a Unicode object. Ideally, this function should return a string that, when passed to `eval()`, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with `'<'` and ending with `'>'` from which both the type and the value of the object can be deduced.

## Inheritance:

This field is inherited by subtypes.

## Default:

When this field is not set, a string of the form `<%s object at %p>` is returned, where `%s` is replaced by the type name, and `%p` by the object's memory address.

`PyNumberMethods *PyTypeObject.tp_as_number`

Pointer to an additional structure that contains fields relevant only to objects which implement the number protocol. These fields are documented in [Number Object Structures](#).

## Inheritance:

The `tp_as_number` field is not inherited, but the contained fields are inherited individually.

`PySequenceMethods *PyTypeObject.tp_as_sequence`

Pointer to an additional structure that contains fields relevant only to objects which implement the sequence protocol. These fields are documented in [Sequence Object Structures](#).

### Inheritance:

The `tp_as_sequence` field is not inherited, but the contained fields are inherited individually.

### [PyMappingMethods](#) \*[PyTypeObject](#).tp\_as\_mapping

Pointer to an additional structure that contains fields relevant only to objects which implement the mapping protocol. These fields are documented in [Mapping Object Structures](#).

### Inheritance:

The `tp_as_mapping` field is not inherited, but the contained fields are inherited individually.

### [hashfunc](#) [PyTypeObject](#).tp\_hash

An optional pointer to a function that implements the built-in function `hash()`.

The signature is the same as for `PyObject_Hash()`:

```
Py_hash_t tp_hash(PyObject *);
```

The value `-1` should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return `-1`.

When this field is not set (and `tp_richcompare` is not set), an attempt to take the hash of the object raises `TypeError`. This is the same as setting it to `PyObject_HashNotImplemented()`.

This field can be set explicitly to `PyObject_HashNotImplemented()` to block inheritance of the hash method from a parent type. This is interpreted as the equivalent of `__hash__ = None` at the Python level,

causing `isinstance(o, collections.Hashable)` to correctly return `False`. Note that the converse is also true - setting `__hash__ = None` on a class at the Python level will result in the `tp_hash` slot being set to `PyObject_HashNotImplemented()`.

### Inheritance:

Group: `tp_hash`, `tp_richcompare`

This field is inherited by subtypes together with `tp_richcompare`: a subtype inherits both of `tp_richcompare` and `tp_hash`, when the subtype's `tp_richcompare` and `tp_hash` are both `NULL`.

`ternaryfunc` `PyTypeObject.tp_call`

An optional pointer to a function that implements calling the object. This should be `NULL` if the object is not callable. The signature is the same as for `PyObject_Call()`:

```
PyObject *tp_call(PyObject *self, PyObject *args, P
```

### Inheritance:

This field is inherited by subtypes.

`reprfunc` `PyTypeObject.tp_str`

An optional pointer to a function that implements the built-in operation `str()`. (Note that `str` is a type now, and `str()` calls the constructor for that type. This constructor calls `PyObject_Str()` to do the actual work, and `PyObject_Str()` will call this handler.)

The signature is the same as for `PyObject_Str()`:

```
PyObject *tp_str(PyObject *self);
```

The function must return a string or a Unicode object. It should be a “friendly” string representation of the object, as this is the representation that will be used, among other things, by the `print()` function.

## Inheritance:

This field is inherited by subtypes.

## Default:

When this field is not set, `PyObject_Repr()` is called to return a string representation.

`getattrofunc` `PyTypeObject.tp_getattro`

An optional pointer to the get-attribute function.

The signature is the same as for `PyObject_GetAttr()`:

```
PyObject *tp_getattro(PyObject *self, PyObject *attr)
```

It is usually convenient to set this field to `PyObject_GenericGetAttr()`, which implements the normal way of looking for object attributes.

## Inheritance:

Group: `tp_getattr`, `tp_getattro`

This field is inherited by subtypes together with `tp_getattr`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

## Default:

`PyBaseObject_Type` uses `PyObject_GenericGetAttr()`.

`setattrofunc` `PyTypeObject.tp_setattro`

An optional pointer to the function for setting and deleting attributes.

The signature is the same as for `PyObject_SetAttr()`:

```
int tp_setattro(PyObject *self, PyObject *attr, PyO
```

In addition, setting *value* to `NULL` to delete an attribute must be supported. It is usually convenient to set this field to `PyObject_GenericSetAttr()`, which implements the normal way of setting object attributes.

### Inheritance:

Group: `tp_setattr`, `tp_setattro`

This field is inherited by subtypes together with `tp_setattr`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

### Default:

`PyBaseObject_Type` uses `PyObject_GenericSetAttr()`.

`PyBufferProcs *PyTypeObject.tp_as_buffer`

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in [Buffer Object Structures](#).

### Inheritance:

The `tp_as_buffer` field is not inherited, but the contained fields are inherited individually.

unsigned long `PyTypeObject.tp_flags`

This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via `tp_as_number`, `tp_as_sequence`, `tp_as_mapping`, and `tp_as_buffer`) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or `NULL` value instead.

### Inheritance:

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type's value of the flag bit is copied into the subtype together with a pointer to the extension structure. The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the `tp_traverse` and `tp_clear` fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the `tp_traverse` and `tp_clear` fields in the subtype exist and have `NULL` values. .. XXX are most flag bits *really* inherited individually?

### Default:

**PyBaseObject\_Type** uses `Py_TPFLAGS_DEFAULT` | `Py_TPFLAGS_BASETYPE`.

### Bit Masks:

The following bit masks are currently defined; these can be ORed together using the `|` operator to form the value of the `tp_flags` field. The macro `PyType_HasFeature()` takes a type and a flags value, `tp` and `f`, and checks whether `tp->tp_flags & f` is non-zero.

#### `Py_TPFLAGS_HEAPTYPE`

This bit is set when the type object itself is allocated on the heap, for example, types created dynamically using `PyType_FromSpec()`. In this case, the `ob_type` field of its instances is considered a reference to the type, and the type object is INCREf'ed when a new instance is created, and DECREf'ed when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance's `ob_type` gets INCREf'ed or DECREf'ed).

### Inheritance:

???

## Py\_TPFLAGS\_BASETYPE

This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a “final” class in Java).

### Inheritance:

???

## Py\_TPFLAGS\_READY

This bit is set when the type object has been fully initialized by `PyType_Ready()`.

### Inheritance:

???

## Py\_TPFLAGS\_READYING

This bit is set while `PyType_Ready()` is in the process of initializing the type object.

### Inheritance:

???

## Py\_TPFLAGS\_HAVE\_GC

This bit is set when the object supports garbage collection. If this bit is set, instances must be created using `PyObject_GC_New` and destroyed using `PyObject_GC_Del()`. More information in section [Supporting Cyclic Garbage Collection](#). This bit also implies that the GC-related fields `tp_traverse` and `tp_clear` are present in the type object.

### Inheritance:

Group: `Py_TPFLAGS_HAVE_GC`, `tp_traverse`, `tp_clear`

The `Py_TPFLAGS_HAVE_GC` flag bit is inherited

together with the `tp_traverse` and `tp_clear` fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the `tp_traverse` and `tp_clear` fields in the subtype exist and have `NULL` values.

## `Py_TPFLAGS_DEFAULT`

This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits:

**`Py_TPFLAGS_HAVE_STACKLESS_EXTENSION`.**

### **Inheritance:**

???

## `Py_TPFLAGS_METHOD_DESCRIPTOR`

This bit indicates that objects behave like unbound methods.

If this flag is set for `type(meth)`, then:

- `meth.__get__(obj, cls)(*args, **kwds)` (with `obj` not `None`) must be equivalent to `meth(obj, *args, **kwds)`.
- `meth.__get__(None, cls)(*args, **kwds)` must be equivalent to `meth(*args, **kwds)`.

This flag enables an optimization for typical method calls like `obj.meth()`: it avoids creating a temporary “bound method” object for `obj.meth`.

*New in version 3.8.*

### **Inheritance:**

This flag is never inherited by types without the `Py_TPFLAGS_IMMUTABLETYPE` flag set. For extension types, it is inherited whenever `tp_descr_get` is

inherited.

#### Py\_TPFLAGS\_MANAGED\_DICT

This bit indicates that instances of the class have a `__dict__` attribute, and that the space for the dictionary is managed by the VM.

If this flag is set, `Py_TPFLAGS_HAVE_GC` should also be set.

*New in version 3.12.*

#### Inheritance:

This flag is inherited unless the `tp_dictoffset` field is set in a superclass.

#### Py\_TPFLAGS\_MANAGED\_WEAKREF

This bit indicates that instances of the class should be weakly referenceable.

*New in version 3.12.*

#### Inheritance:

This flag is inherited unless the `tp_weaklistoffset` field is set in a superclass.

#### Py\_TPFLAGS\_ITEMS\_AT\_END

Only usable with variable-size types, i.e. ones with non-zero `tp_itemsize`.

Indicates that the variable-sized portion of an instance of this type is at the end of the instance's memory area, at an offset of `Py_TYPE(obj) -> tp_basicsize` (which may be different in each subclass).

When setting this flag, be sure that all superclasses either use this memory layout, or are not variable-sized. Python does not check this.

*New in version 3.12.*

### **Inheritance:**

This flag is inherited.

Py\_TPFLAGS\_LONG\_SUBCLASS

Py\_TPFLAGS\_LIST\_SUBCLASS

Py\_TPFLAGS\_TUPLE\_SUBCLASS

Py\_TPFLAGS\_BYTES\_SUBCLASS

Py\_TPFLAGS\_UNICODE\_SUBCLASS

Py\_TPFLAGS\_DICT\_SUBCLASS

Py\_TPFLAGS\_BASE\_EXC\_SUBCLASS

Py\_TPFLAGS\_TYPE\_SUBCLASS

These flags are used by functions such as `PyLong_Check()` to quickly determine if a type is a subclass of a built-in type; such specific checks are faster than a generic check, like `PyObject_IsInstance()`. Custom types that inherit from built-ins should have their `tp_flags` set appropriately, or the code that interacts with such types will behave differently depending on what kind of check is used.

Py\_TPFLAGS\_HAVE\_FINALIZE

This bit is set when the `tp_finalize` slot is present in the type structure.

*New in version 3.4.*

*Deprecated since version 3.8:* This flag isn't necessary anymore, as the interpreter assumes the `tp_finalize`

slot is always present in the type structure.

#### Py\_TPFLAGS\_HAVE\_VECTORCALL

This bit is set when the class implements the [vectorcall protocol](#). See [tp\\_vectorcall\\_offset](#) for details.

##### **Inheritance:**

This bit is inherited if [tp\\_call](#) is also inherited.

*New in version 3.9.*

*Changed in version 3.12:* This flag is now removed from a class when the class's [\\_\\_call\\_\\_\(\)](#) method is reassigned.

This flag can now be inherited by mutable classes.

#### Py\_TPFLAGS\_IMMUTABLETYPE

This bit is set for type objects that are immutable: type attributes cannot be set nor deleted.

[PyType\\_Ready\(\)](#) automatically applies this flag to [static types](#).

##### **Inheritance:**

This flag is not inherited.

*New in version 3.10.*

#### Py\_TPFLAGS\_DISALLOW\_INSTANTIATION

Disallow creating instances of the type: set [tp\\_new](#) to NULL and don't create the [\\_\\_new\\_\\_](#) key in the type dictionary.

The flag must be set before creating the type, not after. For example, it must be set before [PyType\\_Ready\(\)](#) is called on the type.

The flag is set automatically on [static types](#) if [tp\\_base](#)

is NULL or `&PyBaseObject_Type` and `tp_new` is NULL.

### Inheritance:

This flag is not inherited. However, subclasses will not be instantiable unless they provide a non-NULL `tp_new` (which is only possible via the C API).

### Note

To disallow instantiating a class directly but allow instantiating its subclasses (e.g. for an `abstract base class`), do not use this flag. Instead, make `tp_new` only succeed for subclasses.

*New in version 3.10.*

## Py\_TPFLAGS\_MAPPING

This bit indicates that instances of the class may match mapping patterns when used as the subject of a `match` block. It is automatically set when registering or subclassing `collections.abc.Mapping`, and unset when registering `collections.abc.Sequence`.

### Note

`Py_TPFLAGS_MAPPING` and `Py_TPFLAGS_SEQUENCE` are mutually exclusive; it is an error to enable both flags simultaneously.

### Inheritance:

This flag is inherited by types that do not already set `Py_TPFLAGS_SEQUENCE`.

### See also

[PEP 634](https://peps.python.org/pep-0634/) [https://peps.python.org/pep-0634/] – Structural Pattern Matching: Specification

*New in version 3.10.*

## Py\_TPFLAGS\_SEQUENCE

This bit indicates that instances of the class may match sequence patterns when used as the subject of a `match` block. It is automatically set when registering or subclassing `collections.abc.Sequence`, and unset when registering `collections.abc.Mapping`.

### Note

`Py_TPFLAGS_MAPPING` and `Py_TPFLAGS_SEQUENCE` are mutually exclusive; it is an error to enable both flags simultaneously.

### Inheritance:

This flag is inherited by types that do not already set `Py_TPFLAGS_MAPPING`.

### See also

[PEP 634](https://peps.python.org/pep-0634/) [https://peps.python.org/pep-0634/] – Structural Pattern Matching: Specification

*New in version 3.10.*

## Py\_TPFLAGS\_VALID\_VERSION\_TAG

Internal. Do not set or unset this flag. To indicate that a class has changed call `PyType_Modified()`

### Warning

This flag is present in header files, but is an internal feature and should not be used. It will be removed in a future version of CPython

```
const char *PyTypeObject.tp_doc
```

An optional pointer to a NUL-terminated C string giving the docstring for this type object. This is exposed as the `__doc__` attribute on the type and instances of the type.

### Inheritance:

This field is *not* inherited by subtypes.

#### [traverseproc](#) `PyTypeObject.tp_traverse`

An optional pointer to a traversal function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. The signature is:

```
int tp_traverse(PyObject *self, visitproc visit, vo
```

More information about Python's garbage collection scheme can be found in section [Supporting Cyclic Garbage Collection](#).

The `tp_traverse` pointer is used by the garbage collector to detect reference cycles. A typical implementation of a `tp_traverse` function simply calls `Py_VISIT()` on each of the instance's members that are Python objects that the instance owns. For example, this is function `local_traverse()` from the `_thread` extension module:

```
static int
local_traverse(localobject *self, visitproc visit,
{
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that `Py_VISIT()` is called only on those members that can participate in reference cycles. Although there is also a `self->key` member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.

On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it

anyway just so the `gc` module's `get_referents()` function will include it.

### Warning

When implementing `tp_traverse`, only the members that the instance *owns* (by having *strong references* to them) must be visited. For instance, if an object supports weak references via the `tp_weaklist` slot, the pointer supporting the linked list (what `tp_weaklist` points to) must **not** be visited as the instance does not directly own the weak references to itself (the weakreference list is there to support the weak reference machinery, but the instance has no strong reference to the elements inside it, as they are allowed to be removed even if the instance is still alive).

Note that `Py_VISIT()` requires the *visit* and *arg* parameters to `local_traverse()` to have these specific names; don't name them just anything.

Instances of *heap-allocated types* hold a reference to their type. Their traversal function must therefore either visit `Py_TYPE(self)`, or delegate this responsibility by calling `tp_traverse` of another heap-allocated type (such as a heap-allocated superclass). If they do not, the type object may not be garbage-collected.

*Changed in version 3.9:* Heap-allocated types are expected to visit `Py_TYPE(self)` in `tp_traverse`. In earlier versions of Python, due to [bug 40217](https://bugs.python.org/issue40217) [https://bugs.python.org/issue40217], doing this may lead to crashes in subclasses.

### Inheritance:

Group: `Py_TPFLAGS_HAVE_GC`, `tp_traverse`, `tp_clear`

This field is inherited by subtypes together with `tp_clear` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

## `inquiry PyObject.tp_clear`

An optional pointer to a clear function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. The signature is:

```
int tp_clear(PyObject *);
```

The `tp_clear` member function is used to break reference cycles in cyclic garbage detected by the garbage collector. Taken together, all `tp_clear` functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a `tp_clear` function. For example, the tuple type does not implement a `tp_clear` function, because it's possible to prove that no reference cycle can be composed entirely of tuples. Therefore the `tp_clear` functions of other types must be sufficient to break any cycle containing a tuple. This isn't immediately obvious, and there's rarely a good reason to avoid implementing `tp_clear`.

Implementations of `tp_clear` should drop the instance's references to those of its members that may be Python objects, and set its pointers to those members to `NULL`, as in the following example:

```
static int
local_clear(localobject *self)
{
    Py_CLEAR(self->key);
    Py_CLEAR(self->args);
    Py_CLEAR(self->kw);
    Py_CLEAR(self->dict);
    return 0;
}
```

The `Py_CLEAR()` macro should be used, because clearing references is delicate: the reference to the contained object must not be released (via `Py_DECREF()`) until after the pointer to the contained object is set to `NULL`. This is because releasing the reference may cause the contained object to become trash, triggering a chain of reclamation activity that

may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it's possible for such code to reference *self* again, it's important that the pointer to the contained object be NULL at that time, so that *self* knows the contained object can no longer be used. The `Py_CLEAR()` macro performs the operations in a safe order.

Note that `tp_clear` is not *always* called before an instance is deallocated. For example, when reference counting is enough to determine that an object is no longer used, the cyclic garbage collector is not involved and `tp_dealloc` is called directly.

Because the goal of `tp_clear` functions is to break reference cycles, it's not necessary to clear contained objects like Python strings or Python integers, which can't participate in reference cycles. On the other hand, it may be convenient to clear all contained Python objects, and write the type's `tp_dealloc` function to invoke `tp_clear`.

More information about Python's garbage collection scheme can be found in section [Supporting Cyclic Garbage Collection](#).

### Inheritance:

Group: `Py_TPFLAGS_HAVE_GC`, `tp_traverse`, `tp_clear`

This field is inherited by subtypes together with `tp_traverse` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

### `richcmpfunc` `PyTypeObject.tp_richcompare`

An optional pointer to the rich comparison function, whose signature is:

```
PyObject *tp_richcompare(PyObject *self, PyObject *
```

The first parameter is guaranteed to be an instance of the type that is defined by `PyTypeObject`.

The function should return the result of the comparison (usually `Py_True` or `Py_False`). If the comparison is undefined, it must return `Py_NotImplemented`, if another error occurred it must return `NULL` and set an exception condition.

The following constants are defined to be used as the third argument for `tp_richcompare` and for `PyObject_RichCompare()`:

### Comparison

<code>Py_LT</code>
<code>Py_LE</code>
<code>Py_EQ</code>
<code>Py_NE</code>
<code>Py_GT</code>
<code>Py_GE</code>

The following macro is defined to ease writing rich comparison functions:

`Py_RETURN_RICHCOMPARE(VAL_A, VAL_B, op)`

Return `Py_True` or `Py_False` from the function, depending on the result of a comparison. `VAL_A` and `VAL_B` must be orderable by C comparison operators (for example, they may be C ints or floats). The third argument specifies the requested operation, as for `PyObject_RichCompare()`.

The returned value is a new [strong reference](#).

On error, sets an exception and returns `NULL` from the function.

*New in version 3.7.*

### Inheritance:

Group: `tp_hash`, `tp_richcompare`

This field is inherited by subtypes together with `tp_hash`: a

subtype inherits `tp_richcompare` and `tp_hash` when the subtype's `tp_richcompare` and `tp_hash` are both `NULL`.

### Default:

`PyBaseObject_Type` provides a `tp_richcompare` implementation, which may be inherited. However, if only `tp_hash` is defined, not even the inherited function is used and instances of the type will not be able to participate in any comparisons.

### `Py_ssize_t PyObject.tp_weaklistoffset`

While this field is still supported,

`Py_TPFLAGS_MANAGED_WEAKREF` should be used instead, if at all possible.

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by `PyObject_ClearWeakRefs()` and the `PyWeakref_*` functions. The instance structure needs to include a field of type `PyObject*` which is initialized to `NULL`.

Do not confuse this field with `tp_weaklist`; that is the list head for weak references to the type object itself.

It is an error to set both the

`Py_TPFLAGS_MANAGED_WEAKREF` bit and `tp_weaklist`.

### Inheritance:

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via `tp_weaklistoffset`, this should not be a problem.

### Default:

If the `Py_TPFLAGS_MANAGED_WEAKREF` bit is set in the

`tp_dict` field, then `tp_weaklistoffset` will be set to a negative value, to indicate that it is unsafe to use this field.

### `getiterfunc PyTypeObject.tp_iter`

An optional pointer to a function that returns an [iterator](#) for the object. Its presence normally signals that the instances of this type are [iterable](#) (although sequences may be iterable without this function).

This function has the same signature as `PyObject_GetIter()`:

```
PyObject *tp_iter(PyObject *self);
```

#### **Inheritance:**

This field is inherited by subtypes.

### `iternextfunc PyTypeObject.tp_iternext`

An optional pointer to a function that returns the next item in an [iterator](#). The signature is:

```
PyObject *tp_iternext(PyObject *self);
```

When the iterator is exhausted, it must return `NULL`; a [StopIteration](#) exception may or may not be set. When another error occurs, it must return `NULL` too. Its presence signals that the instances of this type are iterators.

Iterator types should also define the `tp_iter` function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as `PyIter_Next()`.

#### **Inheritance:**

This field is inherited by subtypes.

struct `PyMethodDef *PyTypeObject.tp_methods`

An optional pointer to a static NULL-terminated array of `PyMethodDef` structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a method descriptor.

### **Inheritance:**

This field is not inherited by subtypes (methods are inherited through a different mechanism).

struct `PyMemberDef *PyTypeObject.tp_members`

An optional pointer to a static NULL-terminated array of `PyMemberDef` structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a member descriptor.

### **Inheritance:**

This field is not inherited by subtypes (members are inherited through a different mechanism).

struct `PyGetSetDef *PyTypeObject.tp_getset`

An optional pointer to a static NULL-terminated array of `PyGetSetDef` structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a getset descriptor.

### **Inheritance:**

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

`PyTypeObject *PyTypeObject.tp_base`

An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

### Note

Slot initialization is subject to the rules of initializing globals. C99 requires the initializers to be “address constants”. Function designators like `PyType_GenericNew()`, with implicit conversion to a pointer, are valid C99 address constants.

However, the unary ‘&’ operator applied to a non-static variable like `PyBaseObject_Type` is not required to produce an address constant. Compilers may support this (gcc does), MSVC does not. Both compilers are strictly standard conforming in this particular behavior.

Consequently, `tp_base` should be set in the extension module’s init function.

### Inheritance:

This field is not inherited by subtypes (obviously).

### Default:

This field defaults to `&PyBaseObject_Type` (which to Python programmers is known as the type `object`).

`PyObject *PyTypeObject.tp_dict`

The type’s dictionary is stored here by `PyType_Ready()`.

This field should normally be initialized to `NULL` before `PyType_Ready` is called; it may also be initialized to a dictionary containing initial attributes for the type. Once `PyType_Ready()` has initialized the type, extra attributes for the type may be added to this dictionary only if they don’t

correspond to overloaded operations (like `__add__()`). Once initialization for the type has finished, this field should be treated as read-only.

Some types may not store their dictionary in this slot. Use `PyType_GetDict()` to retrieve the dictionary for an arbitrary type.

*Changed in version 3.12:* Internals detail: For static builtin types, this is always `NULL`. Instead, the dict for such types is stored on `PyInterpreterState`. Use `PyType_GetDict()` to get the dict for an arbitrary type.

### Inheritance:

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

### Default:

If this field is `NULL`, `PyType_Ready()` will assign a new dictionary to it.

### Warning

It is not safe to use `PyDict_SetItem()` on or otherwise modify `tp_dict` with the dictionary C-API.

`descrgetfunc` `PyTypeObject.tp_descr_get`

An optional pointer to a “descriptor get” function.

The function signature is:

```
PyObject * tp_descr_get(PyObject *self, PyObject *o
```

### Inheritance:

This field is inherited by subtypes.

`descrsetfunc` `PyTypeObject.tp_descr_set`

An optional pointer to a function for setting and deleting a descriptor's value.

The function signature is:

```
int tp_descr_set(PyObject *self, PyObject *obj, PyO
```

The *value* argument is set to `NULL` to delete the value.

### Inheritance:

This field is inherited by subtypes.

`Py_ssize_t PyTypeObject.tp_dictoffset`

While this field is still supported,

`Py_TPFLAGS_MANAGED_DICT` should be used instead, if at all possible.

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by

`PyObject_GenericGetAttr()`.

Do not confuse this field with `tp_dict`; that is the dictionary for attributes of the type object itself.

The value specifies the offset of the dictionary from the start of the instance structure.

The `tp_dictoffset` should be regarded as write-only. To get the pointer to the dictionary call

`PyObject_GenericGetDict()`. Calling

`PyObject_GenericGetDict()` may need to allocate memory for the dictionary, so it is may be more efficient to call `PyObject_GetAttr()` when accessing an attribute on the object.

It is an error to set both the

`Py_TPFLAGS_MANAGED_WEAKREF` bit and `tp_dictoffset`.

## Inheritance:

This field is inherited by subtypes. A subtype should not override this offset; doing so could be unsafe, if C code tries to access the dictionary at the previous offset. To properly support inheritance, use `Py_TPFLAGS_MANAGED_DICT`.

## Default:

This slot has no default. For `static types`, if the field is `NULL` then no `__dict__` gets created for instances.

If the `Py_TPFLAGS_MANAGED_DICT` bit is set in the `tp_dict` field, then `tp_dictoffset` will be set to `-1`, to indicate that it is unsafe to use this field.

## `initproc PyObject.tp_init`

An optional pointer to an instance initialization function.

This function corresponds to the `__init__()` method of classes. Like `__init__()`, it is possible to create an instance without calling `__init__()`, and it is possible to reinitialize an instance by calling its `__init__()` method again.

The function signature is:

```
int tp_init(PyObject *self, PyObject *args, PyObject
```

The `self` argument is the instance to be initialized; the `args` and `kws` arguments represent positional and keyword arguments of the call to `__init__()`.

The `tp_init` function, if not `NULL`, is called when an instance is created normally by calling its type, after the type's `tp_new` function has returned an instance of the type. If the `tp_new` function returns an instance of some other type that is not a subtype of the original type, no `tp_init` function is called; if `tp_new` returns an instance of a subtype of the original type, the subtype's `tp_init` is called.

Returns `0` on success, `-1` and sets an exception on error.

## Inheritance:

This field is inherited by subtypes.

## Default:

For **static types** this field does not have a default.

**allocfunc** **PyTypeObject.tp\_alloc**

An optional pointer to an instance allocation function.

The function signature is:

```
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t n)
```

## Inheritance:

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement).

## Default:

For dynamic subtypes, this field is always set to **PyType\_GenericAlloc()**, to force a standard heap allocation strategy.

For static subtypes, **PyBaseObject\_Type** uses **PyType\_GenericAlloc()**. That is the recommended value for all statically defined types.

**newfunc** **PyTypeObject.tp\_new**

An optional pointer to an instance creation function.

The function signature is:

```
PyObject *tp_new(PyTypeObject *subtype, PyObject *a
```

The *subtype* argument is the type of the object being created; the *args* and *kws* arguments represent positional and keyword arguments of the call to the type. Note that *subtype* doesn't have to equal the type whose **tp\_new** function is

called; it may be a subtype of that type (but not an unrelated type).

The `tp_new` function should call `subtype->tp_alloc(subtype, nitems)` to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the `tp_init` handler. A good rule of thumb is that for immutable types, all initialization should take place in `tp_new`, while for mutable types, most initialization should be deferred to `tp_init`.

Set the `Py_TPFLAGS_DISALLOW_INSTANTIATION` flag to disallow creating instances of the type in Python.

### Inheritance:

This field is inherited by subtypes, except it is not inherited by `static types` whose `tp_base` is `NULL` or `&PyBaseObject_Type`.

### Default:

For `static types` this field has no default. This means if the slot is defined as `NULL`, the type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

### `freefunc PyTypeObject.tp_free`

An optional pointer to an instance deallocation function. Its signature is:

```
void tp_free(void *self);
```

An initializer that is compatible with this signature is `PyObject_Free()`.

### Inheritance:

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement)

## Default:

In dynamic subtypes, this field is set to a deallocator suitable to match `PyType_GenericAlloc()` and the value of the `Py_TPFLAGS_HAVE_GC` flag bit.

For static subtypes, `PyBaseObject_Type` uses `PyObject_Del()`.

`inquiry PyTypeObject.tp_is_gc`

An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's `tp_flags` field, and check the `Py_TPFLAGS_HAVE_GC` flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return `1` for a collectible instance, and `0` for a non-collectible instance. The signature is:

```
int tp_is_gc(PyObject *self);
```

(The only example of this are types themselves. The metatype, `PyType_Type`, defines this function to distinguish between statically and [dynamically allocated types](#).)

## Inheritance:

This field is inherited by subtypes.

## Default:

This slot has no default. If this field is `NULL`, `Py_TPFLAGS_HAVE_GC` is used as the functional equivalent.

`PyObject *PyTypeObject.tp_bases`

Tuple of base types.

This field should be set to `NULL` and treated as read-only. Python will fill it in when the type is **initialized**.

For dynamically created classes, the `Py_tp_bases` **slot** can be used instead of the *bases* argument of **`PyType_FromSpecWithBases()`**. The argument form is preferred.

### **Warning**

Multiple inheritance does not work well for statically defined types. If you set `tp_bases` to a tuple, Python will not raise an error, but some slots will only be inherited from the first base.

### **Inheritance:**

This field is not inherited.

**`PyObject *`****`PyTypeObject.tp_mro`**

Tuple containing the expanded set of base types, starting with the type itself and ending with **`object`**, in Method Resolution Order.

This field should be set to `NULL` and treated as read-only. Python will fill it in when the type is **initialized**.

### **Inheritance:**

This field is not inherited; it is calculated fresh by **`PyType_Ready()`**.

**`PyObject *`****`PyTypeObject.tp_cache`**

Unused. Internal use only.

### **Inheritance:**

This field is not inherited.

**`void *`****`PyTypeObject.tp_subclasses`**

A collection of subclasses. Internal use only. May be an invalid pointer.

To get a list of subclasses, call the Python method `__subclasses__()`.

*Changed in version 3.12:* For some types, this field does not hold a valid `PyObject*`. The type was changed to `void*` to indicate this.

### **Inheritance:**

This field is not inherited.

`PyObject *``PyTypeObject.tp_weaklist`

Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

*Changed in version 3.12:* Internals detail: For the static builtin types this is always `NULL`, even if weakrefs are added. Instead, the weakrefs for each are stored on `PyInterpreterState`. Use the public C-API or the internal `_PyObject_GET_WEAKREFS_LISTPTR()` macro to avoid the distinction.

### **Inheritance:**

This field is not inherited.

`destructor` `PyTypeObject.tp_del`

This field is deprecated. Use `tp_finalize` instead.

`unsigned int` `PyTypeObject.tp_version_tag`

Used to index into the method cache. Internal use only.

### **Inheritance:**

This field is not inherited.

`destructor` `PyTypeObject.tp_finalize`

An optional pointer to an instance finalization function. Its signature is:

```
void tp_finalize(PyObject *self);
```

If `tp_finalize` is set, the interpreter calls it once when finalizing an instance. It is called either from the garbage collector (if the instance is part of an isolated reference cycle) or just before the object is deallocated. Either way, it is guaranteed to be called before attempting to break reference cycles, ensuring that it finds the object in a sane state.

`tp_finalize` should not mutate the current exception status; therefore, a recommended way to write a non-trivial finalizer is:

```
static void
local_finalize(PyObject *self)
{
    PyObject *error_type, *error_value, *error_trac

    /* Save the current exception, if any. */
    PyErr_Fetch(&error_type, &error_value, &error_t

    /* ... */

    /* Restore the saved exception. */
    PyErr_Restore(error_type, error_value, error_tr
}
```

Also, note that, in a garbage collected Python, `tp_dealloc` may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which `tp_dealloc` is called will own the Global Interpreter Lock (GIL). However, if the object being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called `tp_dealloc` will not

violate any assumptions of the library.

### **Inheritance:**

This field is inherited by subtypes.

*New in version 3.4.*

*Changed in version 3.8:* Before version 3.8 it was necessary to set the `Py_TPFLAGS_HAVE_FINALIZE` flags bit in order for this field to be used. This is no longer required.

### **See also**

“Safe object finalization” ([PEP 442](https://peps.python.org/pep-0442/) [<https://peps.python.org/pep-0442/>])

`vectorcallfunc` `PyTypeObject.tp_vectorcall`

Vectorcall function to use for calls of this type object. In other words, it is used to implement `vectorcall` for `type.__call__`. If `tp_vectorcall` is `NULL`, the default call implementation using `__new__()` and `__init__()` is used.

### **Inheritance:**

This field is never inherited.

*New in version 3.9:* (the field exists since 3.8 but it's only used since 3.9)

unsigned char `PyTypeObject.tp_watched`

Internal. Do not use.

*New in version 3.12.*

## **Static Types**

Traditionally, types defined in C code are *static*, that is, a static

`PyTypeObject` structure is defined directly in code and initialized using `PyType_Ready()`.

This results in types that are limited relative to types defined in Python:

- Static types are limited to one base, i.e. they cannot use multiple inheritance.
- Static type objects (but not necessarily their instances) are immutable. It is not possible to add or modify the type object's attributes from Python.
- Static type objects are shared across [sub-interpreters](#), so they should not include any subinterpreter-specific state.

Also, since `PyTypeObject` is only part of the [Limited API](#) as an opaque struct, any extension modules using static types must be compiled for a specific Python minor version.

## Heap Types

An alternative to [static types](#) is *heap-allocated types*, or *heap types* for short, which correspond closely to classes created by Python's `class` statement. Heap types have the `Py_TPFLAGS_HEAPTYPE` flag set.

This is done by filling a `PyType_Spec` structure and calling `PyType_FromSpec()`, `PyType_FromSpecWithBases()`, `PyType_FromModuleAndSpec()`, or `PyType_FromMetaclass()`.

## Number Object Structures

type `PyNumberMethods`

This structure holds pointers to the functions which an object uses to implement the number protocol. Each function is used by the function of similar name documented in the [Number Protocol](#) section.

Here is the structure definition:

```
typedef struct {
    binaryfunc nb_add;
    binaryfunc nb_subtract;
    binaryfunc nb_multiply;
    binaryfunc nb_remainder;
    binaryfunc nb_divmod;
    ternaryfunc nb_power;
    unaryfunc nb_negative;
    unaryfunc nb_positive;
    unaryfunc nb_absolute;
    inquiry nb_bool;
    unaryfunc nb_invert;
    binaryfunc nb_lshift;
    binaryfunc nb_rshift;
    binaryfunc nb_and;
    binaryfunc nb_xor;
    binaryfunc nb_or;
    unaryfunc nb_int;
    void *nb_reserved;
    unaryfunc nb_float;

    binaryfunc nb_inplace_add;
    binaryfunc nb_inplace_subtract;
    binaryfunc nb_inplace_multiply;
    binaryfunc nb_inplace_remainder;
    ternaryfunc nb_inplace_power;
    binaryfunc nb_inplace_lshift;
    binaryfunc nb_inplace_rshift;
    binaryfunc nb_inplace_and;
    binaryfunc nb_inplace_xor;
    binaryfunc nb_inplace_or;

    binaryfunc nb_floor_divide;
    binaryfunc nb_true_divide;
    binaryfunc nb_inplace_floor_divide;
    binaryfunc nb_inplace_true_divide;
```

```
unaryfunc nb_index;

        binaryfunc nb_matrix_multiply;
        binaryfunc nb_inplace_matrix_multiply;
} PyNumberMethods;
```

### Note

Binary and ternary functions must check the type of all their operands, and implement the necessary conversions (at least one of the operands is an instance of the defined type). If the operation is not defined for the given operands, binary and ternary functions must return `Py_NotImplemented`, if another error occurred they must return `NULL` and set an exception.

### Note

The `nb_reserved` field should always be `NULL`. It was previously called `nb_long`, and was renamed in Python 3.0.1.

`binaryfunc PyNumberMethods.nb_add`

`binaryfunc PyNumberMethods.nb_subtract`

`binaryfunc PyNumberMethods.nb_multiply`

`binaryfunc PyNumberMethods.nb_remainder`

binaryfunc PyNumberMethods.nb\_matrix\_multiply

binaryfunc PyNumberMethods.nb\_inplace\_matrix\_multiply

## Mapping Object Structures

type PyMappingMethods

This structure holds pointers to the functions which an object uses to implement the mapping protocol. It has three members:

lenfunc PyMappingMethods.mp\_length

This function is used by **PyMapping\_Size()** and **PyObject\_Size()**, and has the same signature. This slot may be set to `NULL` if the object has no defined length.

binaryfunc PyMappingMethods.mp\_subscript

This function is used by **PyObject\_GetItem()** and **PySequence\_GetSlice()**, and has the same signature as **PyObject\_GetItem()**. This slot must be filled for the **PyMapping\_Check()** function to return `1`, it can be `NULL`

otherwise.

**objobjargproc** `PyMappingMethods.mp_ass_subscript`

This function is used by `PyObject_SetItem()`, `PyObject_DelItem()`, `PySequence_SetSlice()` and `PySequence_DelSlice()`. It has the same signature as `PyObject_SetItem()`, but `v` can also be set to `NULL` to delete an item. If this slot is `NULL`, the object does not support item assignment and deletion.

## Sequence Object Structures

**type** `PySequenceMethods`

This structure holds pointers to the functions which an object uses to implement the sequence protocol.

**lenfunc** `PySequenceMethods.sq_length`

This function is used by `PySequence_Size()` and `PyObject_Size()`, and has the same signature. It is also used for handling negative indices via the `sq_item` and the `sq_ass_item` slots.

**binaryfunc** `PySequenceMethods.sq_concat`

This function is used by `PySequence_Concat()` and has the same signature. It is also used by the `+` operator, after trying the numeric addition via the `nb_add` slot.

**ssizeargfunc** `PySequenceMethods.sq_repeat`

This function is used by `PySequence_Repeat()` and has the same signature. It is also used by the `*` operator, after trying numeric multiplication via the `nb_multiply` slot.

**ssizeargfunc** `PySequenceMethods.sq_item`

This function is used by `PySequence_GetItem()` and has the same signature. It is also used by

`PyObject_GetItem()`, after trying the subscription via the `mp_subscript` slot. This slot must be filled for the `PySequence_Check()` function to return 1, it can be `NULL` otherwise.

Negative indexes are handled as follows: if the `sq_length` slot is filled, it is called and the sequence length is used to compute a positive index which is passed to `sq_item`. If `sq_length` is `NULL`, the index is passed as is to the function.

`ssizeobjargproc PySequenceMethods.sq_ass_item`

This function is used by `PySequence_SetItem()` and has the same signature. It is also used by `PyObject_SetItem()` and `PyObject_DelItem()`, after trying the item assignment and deletion via the `mp_ass_subscript` slot. This slot may be left to `NULL` if the object does not support item assignment and deletion.

`objobjproc PySequenceMethods.sq_contains`

This function may be used by `PySequence_Contains()` and has the same signature. This slot may be left to `NULL`, in this case `PySequence_Contains()` simply traverses the sequence until it finds a match.

`binaryfunc PySequenceMethods.sq_inplace_concat`

This function is used by `PySequence_InPlaceConcat()` and has the same signature. It should modify its first operand, and return it. This slot may be left to `NULL`, in this case `PySequence_InPlaceConcat()` will fall back to `PySequence_Concat()`. It is also used by the augmented assignment `+=`, after trying numeric in-place addition via the `nb_inplace_add` slot.

`ssizeargfunc PySequenceMethods.sq_inplace_repeat`

This function is used by `PySequence_InPlaceRepeat()` and has the same signature. It should modify its first operand, and return it. This slot may be left to `NULL`, in this case `PySequence_InPlaceRepeat()` will fall back to `PySequence_Repeat()`. It is also used by the augmented

assignment `*=`, after trying numeric in-place multiplication via the `nb_inplace_multiply` slot.

## Buffer Object Structures

type `PyBufferProcs`

This structure holds pointers to the functions required by the [Buffer protocol](#). The protocol defines how an exporter object can expose its internal data to consumer objects.

`getbufferproc PyBufferProcs.bf_getbuffer`

The signature of this function is:

```
int (PyObject *exporter, Py_buffer *view, int flags)
```

Handle a request to *exporter* to fill in *view* as specified by *flags*. Except for point (3), an implementation of this function MUST take these steps:

1. Check if the request can be met. If not, raise `BufferError`, set `view->obj` to `NULL` and return `-1`.
2. Fill in the requested fields.
3. Increment an internal counter for the number of exports.
4. Set `view->obj` to *exporter* and increment `view->obj`.
5. Return `0`.

If *exporter* is part of a chain or tree of buffer providers, two main schemes can be used:

- Re-export: Each member of the tree acts as the exporting object and sets `view->obj` to a new reference to itself.
- Redirect: The buffer request is redirected to the root object of the tree. Here, `view->obj` will be a new reference to the root object.

The individual fields of *view* are described in section [Buffer structure](#), the rules how an exporter must react to specific requests are in section [Buffer request types](#).

All memory pointed to in the [Py\\_buffer](#) structure belongs to the exporter and must remain valid until there are no consumers left. [format](#), [shape](#), [strides](#), [suboffsets](#) and [internal](#) are read-only for the consumer.

[PyBuffer\\_FillInfo\(\)](#) provides an easy way of exposing a simple bytes buffer while dealing correctly with all request types.

[PyObject\\_GetBuffer\(\)](#) is the interface for the consumer that wraps this function.

[releasebufferproc](#) [PyBufferProcs](#).[bf\\_releasebuffer](#)

The signature of this function is:

```
void (PyObject *exporter, Py_buffer *view);
```

Handle a request to release the resources of the buffer. If no resources need to be released,

[PyBufferProcs](#).[bf\\_releasebuffer](#) may be `NULL`.

Otherwise, a standard implementation of this function will take these optional steps:

1. Decrement an internal counter for the number of exports.
2. If the counter is 0, free all memory associated with *view*.

The exporter MUST use the [internal](#) field to keep track of buffer-specific resources. This field is guaranteed to remain constant, while a consumer MAY pass a copy of the original buffer as the *view* argument.

This function MUST NOT decrement `view->obj`, since that is done automatically in [PyBuffer\\_Release\(\)](#) (this scheme is useful for breaking reference cycles).

`PyBuffer_Release()` is the interface for the consumer that wraps this function.

# Async Object Structures

*New in version 3.5.*

type `PyAsyncMethods`

This structure holds pointers to the functions required to implement [awaitable](#) and [asynchronous iterator](#) objects.

Here is the structure definition:

```
typedef struct {
    unaryfunc am_await;
    unaryfunc am_aiter;
    unaryfunc am_anext;
    sendfunc am_send;
} PyAsyncMethods;
```

[unaryfunc](#) `PyAsyncMethods.am_await`

The signature of this function is:

```
PyObject *am_await(PyObject *self);
```

The returned object must be an [iterator](#), i.e.

[PyIter\\_Check\(\)](#) must return 1 for it.

This slot may be set to `NULL` if an object is not an [awaitable](#).

[unaryfunc](#) `PyAsyncMethods.am_aiter`

The signature of this function is:

```
PyObject *am_aiter(PyObject *self);
```

Must return an [asynchronous iterator](#) object. See [\\_\\_anext\\_\\_\(\)](#) for details.

This slot may be set to `NULL` if an object does not implement asynchronous iteration protocol.

**unaryfunc** `PyAsyncMethods.am_anext`

The signature of this function is:

```
PyObject *am_anext(PyObject *self);
```

Must return an **awaitable** object. See `__anext__()` for details. This slot may be set to `NULL`.

**sendfunc** `PyAsyncMethods.am_send`

The signature of this function is:

```
PySendResult am_send(PyObject *self, PyObject *arg,
```

See **`PyIter_Send()`** for details. This slot may be set to `NULL`.

*New in version 3.10.*

## Slot Type typedefs

typedef **`PyObject`** \*(\*`allocfunc`)(**`PyTypeObject`** \*cls, **`Py_ssize_t`** nitems)

*Part of the **Stable ABI**.*

The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with **`ob_refcnt`** set to 1 and **`ob_type`** set to the type argument. If the type's **`tp_itemsize`** is non-zero, the object's **`ob_size`** field should be initialized to *nitems* and the length of the allocated memory block should be `tp_basicsize + nitems*tp_itemsize`, rounded up to a multiple of `sizeof(void*)`; otherwise, *nitems* is not used and the

length of the block should be `tp_basicsize`.

This function should not do any other instance initialization, not even to allocate additional memory; that should be done by `tp_new`.

`typedef void (*destructor)(PyObject*)`

*Part of the [Stable ABI](#).*

`typedef void (*freefunc)(void*)`

See `tp_free`.

`typedef PyObject *(*newfunc)(PyObject*, PyObject*, PyObject*)`

*Part of the [Stable ABI](#).*

See `tp_new`.

`typedef int (*initproc)(PyObject*, PyObject*, PyObject*)`

*Part of the [Stable ABI](#).*

See `tp_init`.

`typedef PyObject *(*reprfunc)(PyObject*)`

*Part of the [Stable ABI](#).*

See `tp_repr`.

`typedef PyObject *(*getattrfunc)(PyObject *self, char *attr)`

*Part of the [Stable ABI](#).*

Return the value of the named attribute for the object.

`typedef int (*setattrfunc)(PyObject *self, char *attr, PyObject *value)`

*Part of the [Stable ABI](#).*

Set the value of the named attribute for the object. The value argument is set to `NULL` to delete the attribute.

`typedef PyObject *(*getattrofunc)(PyObject *self, PyObject *attr)`

*Part of the [Stable ABI](#).*

Return the value of the named attribute for the object.

See [tp\\_getattro](#).

```
typedef int (*setattrofunc)(PyObject *self, PyObject *attr, PyObject  
*value)
```

*Part of the [Stable ABI](#).*

Set the value of the named attribute for the object. The value argument is set to `NULL` to delete the attribute.

See [tp\\_setattro](#).

```
typedef PyObject *(*descrgetfunc)(PyObject*, PyObject*,  
PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_descr\\_get](#).

```
typedef int (*descrsetfunc)(PyObject*, PyObject*, PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_descr\\_set](#).

```
typedef Py_hash_t (*hashfunc)(PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_hash](#).

```
typedef PyObject *(*richcmpfunc)(PyObject*, PyObject*, int)
```

*Part of the [Stable ABI](#).*

See [tp\\_richcompare](#).

```
typedef PyObject *(*getiterfunc)(PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_iter](#).

```
typedef PyObject *(*iternextfunc)(PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_iternext](#).

```
typedef Py_ssize_t (*lenfunc)(PyObject*)
```

*Part of the [Stable ABI](#).*

`typedef int (*getbufferproc)(PyObject*, Py_buffer*, int)`

*Part of the [Stable ABI](#) since version 3.12.*

`typedef void (*releasebufferproc)(PyObject*, Py_buffer*)`

*Part of the [Stable ABI](#) since version 3.12.*

`typedef PyObject* (*unaryfunc)(PyObject*)`

*Part of the [Stable ABI](#).*

`typedef PyObject* (*binaryfunc)(PyObject*, PyObject*)`

*Part of the [Stable ABI](#).*

`typedef PySendResult (*sendfunc)(PyObject*, PyObject*,  
PyObject**)`

See [am\\_send](#).

`typedef PyObject* (*ternaryfunc)(PyObject*, PyObject*, PyObject*)`

*Part of the [Stable ABI](#).*

`typedef PyObject* (*ssizeargfunc)(PyObject*, Py_ssize_t)`

*Part of the [Stable ABI](#).*

`typedef int (*ssizeobjargproc)(PyObject*, Py_ssize_t, PyObject*)`

*Part of the [Stable ABI](#).*

`typedef int (*objobjproc)(PyObject*, PyObject*)`

*Part of the [Stable ABI](#).*

`typedef int (*objobjargproc)(PyObject*, PyObject*, PyObject*)`

*Part of the [Stable ABI](#).*

## Examples

The following are simple examples of Python type definitions. They include common usage you may encounter. Some demonstrate tricky corner cases. For more examples, practical info, and a tutorial, see [Defining Extension Types: Tutorial](#) and [Defining Extension Types: Assorted Topics](#).

A basic [static type](#):

```
typedef struct {
    PyObject_HEAD
    const char *data;
} PyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject),
    .tp_doc = PyDoc_STR("My objects"),
    .tp_new = myobj_new,
    .tp_dealloc = (destructor)myobj_dealloc,
    .tp_repr = (reprfunc)myobj_repr,
};
```

You may also find older code (especially in the CPython code base) with a more verbose initializer:

```
static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "mymod.MyObject",           /* tp_name */
    sizeof(MyObject),           /* tp_basicsize */
    0,                           /* tp_itemsize */
    (destructor)myobj_dealloc,  /* tp_dealloc */
    0,                           /* tp_vectorcall_offset */
    0,                           /* tp_getattr */
    0,                           /* tp_setattr */
    0,                           /* tp_as_async */
    (reprfunc)myobj_repr,       /* tp_repr */
    0,                           /* tp_as_number */
    0,                           /* tp_as_sequence */
};
```

```

0, /* tp_as_mapping */
0, /* tp_hash */
0, /* tp_call */
0, /* tp_str */
0, /* tp_getattro */
0, /* tp_setattro */
0, /* tp_as_buffer */
0, /* tp_flags */
PyDoc_STR("My objects"), /* tp_doc */
0, /* tp_traverse */
0, /* tp_clear */
0, /* tp_richcompare */
0, /* tp_weaklistoffset */
0, /* tp_iter */
0, /* tp_iternext */
0, /* tp_methods */
0, /* tp_members */
0, /* tp_getset */
0, /* tp_base */
0, /* tp_dict */
0, /* tp_descr_get */
0, /* tp_descr_set */
0, /* tp_dictoffset */
0, /* tp_init */
0, /* tp_alloc */
myobj_new, /* tp_new */
};

```

A type that supports weakrefs, instance dicts, and hashing:

```

typedef struct {
    PyObject_HEAD
    const char *data;
} PyObject;

static PyTypeObject PyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(PyObject),

```

```

        .tp_doc = PyDoc_STR("My objects"),
        .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE
                    Py_TPFLAGS_HAVE_GC | Py_TPFLAGS_MANAGED_DICT |
                    Py_TPFLAGS_MANAGED_WEAKREF,
        .tp_new = myobj_new,
        .tp_traverse = (traverseproc)myobj_traverse,
        .tp_clear = (inquiry)myobj_clear,
        .tp_alloc = PyType_GenericNew,
        .tp_dealloc = (destructor)myobj_dealloc,
        .tp_repr = (reprfunc)myobj_repr,
        .tp_hash = (hashfunc)myobj_hash,
        .tp_richcompare = PyBaseObject_Type.tp_richcompare,
};

```

A str subclass that cannot be subclassed and cannot be called to create instances (e.g. uses a separate factory func) using **Py\_TPFLAGS\_DISALLOW\_INSTANTIATION** flag:

```

typedef struct {
    PyUnicodeObject raw;
    char *extra;
} MyStr;

static PyTypeObject MyStr_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyStr",
    .tp_basicsize = sizeof(MyStr),
    .tp_base = NULL, // set to &PyUnicode_Type in modul
    .tp_doc = PyDoc_STR("my custom str"),
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_DISALLOW
    .tp_repr = (reprfunc)myobj_repr,
};

```

The simplest **static type** with fixed-length instances:

```

typedef struct {
    PyObject_HEAD
} MyObject;

```

```
static PyObjectType MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
};
```

The simplest **static type** with variable-length instances:

```
typedef struct {
    PyObject_VAR_HEAD
    const char *data[1];
} MyObject;

static PyObjectType MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject) - sizeof(char *),
    .tp_itemsize = sizeof(char *),
};
```

# Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

To create a container type, the `tp_flags` field of the type object must include the `Py_TPFLAGS_HAVE_GC` and provide an implementation of the `tp_traverse` handler. If instances of the type are mutable, a `tp_clear` implementation must also be provided.

## `Py_TPFLAGS_HAVE_GC`

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using `PyObject_GC_New` or `PyObject_GC_NewVar`.
2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack()` must be called.

2. The object's memory must be deallocated using `PyObject_GC_Del()`.

### Warning

If a type adds the `Py_TPFLAGS_HAVE_GC`, then it *must* implement at least a `tp_traverse` handler or explicitly use one from its subclass or subclasses.

When calling `PyType_Ready()` or some of the APIs that indirectly call it like `PyType_FromSpecWithBases()` or `PyType_FromSpec()` the interpreter will automatically populate the `tp_flags`, `tp_traverse` and `tp_clear` fields if the type inherits from a class that implements the garbage collector protocol and the child class does *not* include the `Py_TPFLAGS_HAVE_GC` flag.

`PyObject_GC_New(TYPE, typeobj)`

Analogous to `PyObject_New` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

`PyObject_GC_NewVar(TYPE, typeobj, size)`

Analogous to `PyObject_NewVar` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

`PyObject *PyUnstable_Object_GC_NewWithExtraData(PyTypeObject *type, size_t extra_size)`

*This is **Unstable API**. It may change without warning in minor releases.*

Analogous to `PyObject_GC_New` but allocates *extra\_size* bytes at the end of the object (at offset `tp_basicsize`). The allocated memory is initialized to zeros, except for the **Python object header**.

The extra data will be deallocated with the object, but

otherwise it is not managed by Python.

### Warning

The function is marked as unstable because the final mechanism for reserving extra data after an instance is not yet decided. For allocating a variable number of fields, prefer using `PyVarObject` and `tp_itemsize` instead.

*New in version 3.12.*

`TYPE *PyObject_GC_Resize(TYPE, PyVarObject *op, Py_ssize_t newsize)`

Resize an object allocated by `PyObject_NewVar`. Returns the resized object or `NULL` on failure. `op` must not be tracked by the collector yet.

`void PyObject_GC_Track(PyObject *op)`

*Part of the [Stable ABI](#).*

Adds the object `op` to the set of container objects tracked by the collector. The collector can run at unexpected times so objects must be valid while being tracked. This should be called once all the fields followed by the `tp_traverse` handler become valid, usually near the end of the constructor.

`int PyObject_IS_GC(PyObject *obj)`

Returns non-zero if the object implements the garbage collector protocol, otherwise returns 0.

The object cannot be tracked by the garbage collector if this function returns 0.

`int PyObject_GC_IsTracked(PyObject *op)`

*Part of the [Stable ABI](#) since version 3.9.*

Returns 1 if the object type of `op` implements the GC protocol and `op` is being currently tracked by the garbage collector and 0 otherwise.

This is analogous to the Python function `gc.is_tracked()`.

*New in version 3.9.*

```
int PyObject_GC_IsFinalized(PyObject *op)
```

*Part of the [Stable ABI](#) since version 3.9.*

Returns 1 if the object type of *op* implements the GC protocol and *op* has been already finalized by the garbage collector and 0 otherwise.

This is analogous to the Python function `gc.is_finalized()`.

*New in version 3.9.*

```
void PyObject_GC_Del(void *op)
```

*Part of the [Stable ABI](#).*

Releases memory allocated to an object using `PyObject_GC_New` or `PyObject_GC_NewVar`.

```
void PyObject_GC_UnTrack(void *op)
```

*Part of the [Stable ABI](#).*

Remove the object *op* from the set of container objects tracked by the collector. Note that `PyObject_GC_Track()` can be called again on this object to add it back to the set of tracked objects. The deallocator (`tp_dealloc` handler) should call this for the object before any of the fields used by the `tp_traverse` handler become invalid.

*Changed in version 3.8:* The `_PyObject_GC_TRACK()` and `_PyObject_GC_UNTRACK()` macros have been removed from the public C API.

The `tp_traverse` handler accepts a function parameter of this type:

```
typedef int (*visitproc)(PyObject *object, void *arg)
```

*Part of the [Stable ABI](#).*

Type of the visitor function passed to the `tp_traverse` handler. The function should be called with an object to traverse as *object* and the third parameter to the `tp_traverse` handler as *arg*. The Python core uses several visitor functions to implement cyclic garbage detection; it's not expected that users will need to write their own visitor functions.

The `tp_traverse` handler must have the following type:

```
typedef int (*traverseproc)(PyObject *self, visitproc visit, void *arg)
```

*Part of the [Stable ABI](#).*

Traversal function for a container object. Implementations must call the *visit* function for each object directly contained by *self*, with the parameters to *visit* being the contained object and the *arg* value passed to the handler. The *visit* function must not be called with a `NULL` object argument. If *visit* returns a non-zero value that value should be returned immediately.

To simplify writing `tp_traverse` handlers, a `Py_VISIT()` macro is provided. In order to use this macro, the `tp_traverse` implementation must name its arguments exactly *visit* and *arg*:

```
void Py_VISIT(PyObject *o)
```

If *o* is not `NULL`, call the *visit* callback, with arguments *o* and *arg*. If *visit* returns a non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```
static int
my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

The `tp_clear` handler must be of the `inquiry` type, or `NULL` if the object is immutable.

```
typedef int (*inquiry)(PyObject *self)
```

*Part of the [Stable ABI](#).*

Drop references that may have created reference cycles.

Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don't just call [Py\\_DECREF\(\)](#) on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.

## Controlling the Garbage Collector State

The C-API provides the following functions for controlling garbage collection runs.

```
Py_ssize_t PyGC_Collect(void)
```

*Part of the [Stable ABI](#).*

Perform a full garbage collection, if the garbage collector is enabled. (Note that [gc.collect\(\)](#) runs it unconditionally.)

Returns the number of collected + unreachable objects which cannot be collected. If the garbage collector is disabled or already collecting, returns 0 immediately. Errors during garbage collection are passed to [sys.unraisablehook](#). This function does not raise exceptions.

```
int PyGC_Enable(void)
```

*Part of the [Stable ABI](#) since version 3.10.*

Enable the garbage collector: similar to [gc.enable\(\)](#).

Returns the previous state, 0 for disabled and 1 for enabled.

*New in version 3.10.*

```
int PyGC_Disable(void)
```

*Part of the [Stable ABI](#) since version 3.10.*

Disable the garbage collector: similar to [gc.disable\(\)](#).

Returns the previous state, 0 for disabled and 1 for enabled.

*New in version 3.10.*

`int PyGC_IsEnabled(void)`

*Part of the [Stable ABI](#) since version 3.10.*

Query the state of the garbage collector: similar to [gc.isenabled\(\)](#). Returns the current state, 0 for disabled and 1 for enabled.

*New in version 3.10.*

## Querying Garbage Collector State

The C-API provides the following interface for querying information about the garbage collector.

`void PyUnstable_GC_VisitObjects(gcvisitobjects\_t callback, void *arg)`

*This is [Unstable API](#). It may change without warning in minor releases.*

Run supplied *callback* on all live GC-capable objects. *arg* is passed through to all invocations of *callback*.

### Warning

If new objects are (de)allocated by the callback it is undefined if they will be visited.

Garbage collection is disabled during operation. Explicitly running a collection in the callback may lead to undefined behaviour e.g. visiting the same objects multiple times or not at all.

*New in version 3.12.*

`typedef int (*gcvisitobjects_t)(PyObject *object, void *arg)`

Type of the visitor function to be passed to

`PyUnstable_GC_VisitObjects()`. *arg* is the same as the *arg* passed to `PyUnstable_GC_VisitObjects`. Return 0 to continue iteration, return 1 to stop iteration. Other return values are reserved for now so behavior on returning anything else is undefined.

*New in version 3.12.*

# API and ABI Versioning

CPython exposes its version number in the following macros. Note that these correspond to the version code is **built** with, not necessarily the version used at **run time**.

See [C API Stability](#) for a discussion of API and ABI stability across versions.

PY\_MAJOR\_VERSION

The 3 in 3.4.1a2.

PY\_MINOR\_VERSION

The 4 in 3.4.1a2.

PY\_MICRO\_VERSION

The 1 in 3.4.1a2.

PY\_RELEASE\_LEVEL

The a in 3.4.1a2. This can be 0xA for alpha, 0xB for beta, 0xC for release candidate or 0xF for final.

PY\_RELEASE\_SERIAL

The 2 in 3.4.1a2. Zero for final releases.

PY\_VERSION\_HEX

The Python version number encoded in a single integer.

The underlying version information can be found by treating it as a 32 bit number in the following manner:

**Python 3.4.1a2**  
(3 4 1 a 2)

---

0x00000003 MAJOR\_VERSION

---

0x00000004 MINOR\_VERSION

---

0x00000001 MICRO\_VERSION

---

~~25-28~~ `RELEASE_LEVEL`

~~29-32~~ `RELEASE_SERIAL`

---

Thus 3.4.1a2 is hexversion 0x030401a2 and 3.10.0 is hexversion 0x030a00f0.

Use this for numeric comparisons, e.g. `#if  
PY_VERSION_HEX >= ...`

This version is also available via the symbol `Py_Version`.

`const unsigned long Py_Version`

*Part of the [Stable ABI](#) since version 3.11.*

The Python runtime version number encoded in a single constant integer, with the same format as the `PY_VERSION_HEX` macro. This contains the Python version used at run time.

*New in version 3.11.*

All the given macros are defined in [Include/patchlevel.h](#) [<https://github.com/python/cpython/tree/3.12/Include/patchlevel.h>].

# Installing Python Modules

## Email

[distutils-sig@python.org](mailto:distutils-sig@python.org)

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the installation part of the process. For a guide to creating and sharing your own Python projects, refer to the [Python packaging user guide](https://packaging.python.org/en/latest/tutorials/packaging-projects/) [https://packaging.python.org/en/latest/tutorials/packaging-projects/].

## Note

For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.

## Key terms

- `pip` is the preferred installer program. Starting with Python 3.4, it is included by default with the Python binary installers.
- A *virtual environment* is a semi-isolated Python environment that allows packages to be installed for use by a particular application, rather than being installed system wide.

- `venv` is the standard tool for creating virtual environments, and has been part of Python since Python 3.3. Starting with Python 3.4, it defaults to installing `pip` into all created virtual environments.
- `virtualenv` is a third party alternative (and predecessor) to `venv`. It allows virtual environments to be used on versions of Python prior to 3.4, which either don't provide `venv` at all, or aren't able to automatically install `pip` into created environments.
- The [Python Package Index](https://pypi.org/) [https://pypi.org/] is a public repository of open source licensed packages made available for use by other Python users.
- the [Python Packaging Authority](https://www.pypa.io/) [https://www.pypa.io/] is the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards. They maintain a variety of tools, documentation, and issue trackers on [GitHub](https://github.com/pypa/) [https://github.com/pypa/].
- `distutils` is the original build and distribution system first added to the Python standard library in 1998. While direct use of `distutils` is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).

*Changed in version 3.5:* The use of `venv` is now recommended for creating virtual environments.

## See also

[Python Packaging User Guide: Creating and using virtual environments](https://packaging.python.org/installing/#creating-virtual-environments) [https://packaging.python.org/installing/#creating-virtual-environments]

## Basic usage

The standard packaging tools are all designed to be used from the

command line.

The following command will install the latest version of a module and its dependencies from the Python Package Index:

```
python -m pip install SomePackage
```

### Note

For POSIX users (including macOS and Linux users), the examples in this guide assume the use of a [virtual environment](#).

For Windows users, the examples in this guide assume that the option to adjust the system PATH environment variable was selected when installing Python.

It's also possible to specify an exact or minimum version directly on the command line. When using comparator operators such as `>`, `<` or some other special character which get interpreted by shell, the package name and the version should be enclosed within double quotes:

```
python -m pip install SomePackage==1.0.4      # specific version
python -m pip install "SomePackage>=1.0.4"    # minimum version
```

Normally, if a suitable module is already installed, attempting to install it again will have no effect. Upgrading existing modules must be requested explicitly:

```
python -m pip install --upgrade SomePackage
```

More information and resources regarding `pip` and its capabilities can be found in the [Python Packaging User Guide](https://packaging.python.org/) [https://packaging.python.org/].

Creation of virtual environments is done through the [venv](#) module. Installing packages into an active virtual environment uses the commands shown above.

### See also

## How do I ...?

These are quick answers or links for some common tasks.

### **... install `pip` in versions of Python prior to Python 3.4?**

Python only started bundling `pip` with Python 3.4. For earlier versions, `pip` needs to be “bootstrapped” as described in the Python Packaging User Guide.

#### **See also**

[Python Packaging User Guide: Requirements for Installing Packages](https://packaging.python.org/installing/#requirements-for-installing-packages) [https://packaging.python.org/installing/#requirements-for-installing-packages]

### **... install packages just for the current user?**

Passing the `--user` option to `python -m pip install` will install a package just for the current user, rather than for all users of the system.

### **... install scientific Python packages?**

A number of scientific Python packages have complex binary dependencies, and aren’t currently easy to install using `pip` directly. At this point in time, it will often be easier for users to install these packages by [other means](https://packaging.python.org/science/) [https://packaging.python.org/science/] rather than attempting to install them with `pip`.

#### **See also**

[Python Packaging User Guide: Installing Scientific Packages](https://packaging.python.org/science/) [https://packaging.python.org/science/]

## ... work with multiple versions of Python installed in parallel?

On Linux, macOS, and other POSIX systems, use the versioned Python commands in combination with the `-m` switch to run the appropriate copy of `pip`:

```
python2      -m pip install SomePackage # default Python 2
python2.7    -m pip install SomePackage # specifically Python 2.7
python3      -m pip install SomePackage # default Python 3
python3.4    -m pip install SomePackage # specifically Python 3.4
```

Appropriately versioned `pip` commands may also be available.

On Windows, use the `py` Python launcher in combination with the `-m` switch:

```
py -2      -m pip install SomePackage # default Python 2
py -2.7    -m pip install SomePackage # specifically Python 2.7
py -3      -m pip install SomePackage # default Python 3
py -3.4    -m pip install SomePackage # specifically Python 3.4
```

## Common installation issues

### Installing into the system Python on Linux

On Linux systems, a Python installation will typically be included as part of the distribution. Installing into this Python installation requires root access to the system, and may interfere with the operation of the system package manager and other components of the system if a component is unexpectedly upgraded using `pip`.

On such systems, it is often better to use a virtual environment or a per-user installation when installing packages with `pip`.

### Pip not installed

It is possible that `pip` does not get installed by default. One potential fix is:

```
python -m ensurepip --default-pip
```

There are also additional resources for [installing pip](https://packaging.python.org/en/latest/tutorials/installing-packages/#ensure-pip-setuptools-and-wheel-are-up-to-date). [https://packaging.python.org/en/latest/tutorials/installing-packages/#ensure-pip-setuptools-and-wheel-are-up-to-date]

## Installing binary extensions

Python has typically relied heavily on source based distribution, with end users being expected to compile extension modules from source as part of the installation process.

With the introduction of support for the binary `wheel` format, and the ability to publish wheels for at least Windows and macOS through the Python Package Index, this problem is expected to diminish over time, as users are more regularly able to install pre-built extensions rather than needing to build them themselves.

Some of the solutions for installing [scientific software](https://packaging.python.org/science/) [https://packaging.python.org/science/] that are not yet available as pre-built `wheel` files may also help with obtaining other binary extensions without needing to build them locally.

# Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project's HOWTO collection, this collection is an effort to foster documentation that's more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- [How to port Python 2 Code to Python 3](#)
- [Porting Extension Modules to Python 3](#)
- [Curses Programming with Python](#)
- [Descriptor HowTo Guide](#)
- [Enum HOWTO](#)
- [Functional Programming HOWTO](#)
- [Logging HOWTO](#)
- [Logging Cookbook](#)
- [Regular Expression HOWTO](#)
- [Socket Programming HOWTO](#)
- [Sorting HOW TO](#)
- [Unicode HOWTO](#)
- [HOWTO Fetch Internet Resources Using The urllib Package](#)
- [Argparse Tutorial](#)
- [An introduction to the ipaddress module](#)
- [Instrumenting CPython with DTrace and SystemTap](#)
- [Python support for the Linux \*\*perf\*\* profiler](#)
- [Annotations Best Practices](#)
- [Isolating Extension Modules](#)

# How to port Python 2 Code to Python 3

author

Brett Cannon

## Abstract

Python 2 reached its official end-of-life at the start of 2020. This means that no new bug reports, fixes, or changes will be made to Python 2 - it's no longer supported.

This guide is intended to provide you with a path to Python 3 for your code, that includes compatibility with Python 2 as a first step.

If you are looking to port an extension module instead of pure Python code, please see [Porting Extension Modules to Python 3](#).

The archived [python-porting](#) [<https://mail.python.org/pipermail/python-porting/>] mailing list may contain some useful guidance.

## The Short Explanation

To achieve Python 2/3 compatibility in a single code base, the basic steps are:

1. Only worry about supporting Python 2.7
2. Make sure you have good test coverage ([coverage.py](#) [<https://pypi.org/project/coverage>] can help; `python -m pip install coverage`)
3. Learn the differences between Python 2 and 3
4. Use [Futurize](#) [[https://python-future.org/automatic\\_conversion.html](https://python-future.org/automatic_conversion.html)] (or [Modernize](#) [<https://python-modernize.readthedocs.io/>]) to update

- your code (e.g. `python -m pip install future`)
5. Use [Pylint](https://pypi.org/project/pylint) [https://pypi.org/project/pylint] to help make sure you don't regress on your Python 3 support (`python -m pip install pylint`)
  6. Use [caniusepython3](https://pypi.org/project/caniusepython3) [https://pypi.org/project/caniusepython3] to find out which of your dependencies are blocking your use of Python 3 (`python -m pip install caniusepython3`)
  7. Once your dependencies are no longer blocking you, use continuous integration to make sure you stay compatible with Python 2 and 3 ([tox](https://pypi.org/project/tox) [https://pypi.org/project/tox] can help test against multiple versions of Python; `python -m pip install tox`)
  8. Consider using optional static type checking to make sure your type usage works in both Python 2 and 3 (e.g. use [mypy](https://mypy-lang.org/) [https://mypy-lang.org/] to check your typing under both Python 2 and Python 3; `python -m pip install mypy`).

## Note

Note: Using `python -m pip install` guarantees that the `pip` you invoke is the one installed for the Python currently in use, whether it be a system-wide `pip` or one installed within a [virtual environment](#).

## Details

Even if other factors - say, dependencies over which you have no control - still require you to support Python 2, that does not prevent you taking the step of including Python 3 support.

Most changes required to support Python 3 lead to cleaner code using newer practices even in Python 2 code.

## Different versions of Python 2

Ideally, your code should be compatible with Python 2.7, which was the last supported version of Python 2.

Some of the tools mentioned in this guide will not work with

## Python 2.6.

If absolutely necessary, the [six](https://pypi.org/project/six) [https://pypi.org/project/six] project can help you support Python 2.5 and 3 simultaneously. Do realize, though, that nearly all the projects listed in this guide will not be available to you.

If you are able to skip Python 2.5 and older, the required changes to your code will be minimal. At worst you will have to use a function instead of a method in some instances or have to import a function instead of using a built-in one.

## Make sure you specify the proper version support in your `setup.py` file

In your `setup.py` file you should have the proper [trove classifier](https://pypi.org/classifiers) [https://pypi.org/classifiers] specifying what versions of Python you support. As your project does not support Python 3 yet you should at least have `Programming Language :: Python :: 2 :: Only` specified. Ideally you should also specify each major/minor version of Python that you do support, e.g. `Programming Language :: Python :: 2.7`.

## Have good test coverage

Once you have your code supporting the oldest version of Python 2 you want it to, you will want to make sure your test suite has good coverage. A good rule of thumb is that if you want to be confident enough in your test suite that any failures that appear after having tools rewrite your code are actual bugs in the tools and not in your code. If you want a number to aim for, try to get over 80% coverage (and don't feel bad if you find it hard to get better than 90% coverage). If you don't already have a tool to measure test coverage then [coverage.py](https://pypi.org/project/coverage) [https://pypi.org/project/coverage] is recommended.

## Be aware of the differences between Python 2 and 3

Once you have your code well-tested you are ready to begin porting your code to Python 3! But to fully understand how your code is going to change and what you want to look out for while you code,

you will want to learn what changes Python 3 makes in terms of Python 2.

Some resources for understanding the differences and their implications for your code:

- the “[What’s New](#)” doc for each release of Python 3
- the [Porting to Python 3](http://python3porting.com/) [http://python3porting.com/] book (which is free online)
- the handy [cheat sheet](https://python-future.org/compatible_idioms.html) [https://python-future.org/compatible\_idioms.html] from the Python-Future project.

## Update your code

There are tools available that can port your code automatically.

[Futurize](https://python-future.org/automatic_conversion.html) [https://python-future.org/automatic\_conversion.html] does its best to make Python 3 idioms and practices exist in Python 2, e.g. backporting the `bytes` type from Python 3 so that you have semantic parity between the major versions of Python. This is the better approach for most cases.

[Modernize](https://python-modernize.readthedocs.io/) [https://python-modernize.readthedocs.io/], on the other hand, is more conservative and targets a Python 2/3 subset of Python, directly relying on [six](https://pypi.org/project/six) [https://pypi.org/project/six] to help provide compatibility.

A good approach is to run the tool over your test suite first and visually inspect the diff to make sure the transformation is accurate. After you have transformed your test suite and verified that all the tests still pass as expected, then you can transform your application code knowing that any tests which fail is a translation failure.

Unfortunately the tools can’t automate everything to make your code work under Python 3, and you will also need to read the tools’ documentation in case some options you need are turned off by default.

Key issues to be aware of and check for:

## Division

In Python 3, `5 / 2 == 2.5` and not `2` as it was in Python 2; all division between `int` values result in a `float`. This change has actually been planned since Python 2.2 which was released in 2002. Since then users have been encouraged to add `from __future__ import division` to any and all files which use the `/` and `//` operators or to be running the interpreter with the `-Q` flag. If you have not been doing this then you will need to go through your code and do two things:

1. Add `from __future__ import division` to your files
2. Update any division operator as necessary to either use `//` to use floor division or continue using `/` and expect a `float`

The reason that `/` isn't simply translated to `//` automatically is that if an object defines a `__truediv__` method but not `__floordiv__` then your code would begin to fail (e.g. a user-defined class that uses `/` to signify some operation but not `//` for the same thing or at all).

## Text versus binary data

In Python 2 you could use the `str` type for both text and binary data. Unfortunately this confluence of two different concepts could lead to brittle code which sometimes worked for either kind of data, sometimes not. It also could lead to confusing APIs if people didn't explicitly state that something that accepted `str` accepted either text or binary data instead of one specific type. This complicated the situation especially for anyone supporting multiple languages as APIs wouldn't bother explicitly supporting `unicode` when they claimed text data support.

Python 3 made text and binary data distinct types that cannot simply be mixed together. For any code that deals only with text or only binary data, this separation doesn't pose an issue. But for code that has to deal with both, it does mean you might have to now care about when you are using text compared to binary data, which is why this cannot be entirely automated.

Decide which APIs take text and which take binary (it is **highly** recommended you don't design APIs that can take both due to the

difficulty of keeping the code working; as stated earlier it is difficult to do well). In Python 2 this means making sure the APIs that take text can work with `unicode` and those that work with binary data work with the `bytes` type from Python 3 (which is a subset of `str` in Python 2 and acts as an alias for `bytes` type in Python 2). Usually the biggest issue is realizing which methods exist on which types in Python 2 and 3 simultaneously (for text that's `unicode` in Python 2 and `str` in Python 3, for binary that's `str/bytes` in Python 2 and `bytes` in Python 3).

The following table lists the **unique** methods of each data type across Python 2 and 3 (e.g., the `decode()` method is usable on the equivalent binary data type in either Python 2 or 3, but it can't be used by the textual data type consistently between Python 2 and 3 because `str` in Python 3 doesn't have the method). Do note that as of Python 3.5 the `__mod__` method was added to the `bytes` type.

<b>Textual data</b>	
<code>decode</code>	
<code>encode</code>	
<code>format</code>	
<code>isdecimal</code>	
<code>isnumeric</code>	

Making the distinction easier to handle can be accomplished by encoding and decoding between binary data and text at the edge of your code. This means that when you receive text in binary data, you should immediately decode it. And if your code needs to send text as binary data then encode it as late as possible. This allows your code to work with only text internally and thus eliminates having to keep track of what type of data you are working with.

The next issue is making sure you know whether the string literals in your code represent text or binary data. You should add a `b` prefix to any literal that presents binary data. For text you should add a `u` prefix to the text literal. (There is a [\\_\\_future\\_\\_](#) import to force all unspecified literals to be Unicode, but usage has shown it isn't as effective as adding a `b` or `u` prefix to all literals explicitly)

You also need to be careful about opening files. Possibly you have

not always bothered to add the `b` mode when opening a binary file (e.g., `rb` for binary reading). Under Python 3, binary files and text files are clearly distinct and mutually incompatible; see the `io` module for details. Therefore, you **must** make a decision of whether a file will be used for binary access (allowing binary data to be read and/or written) or textual access (allowing text data to be read and/or written). You should also use `io.open()` for opening files instead of the built-in `open()` function as the `io` module is consistent from Python 2 to 3 while the built-in `open()` function is not (in Python 3 it's actually `io.open()`). Do not bother with the outdated practice of using `codecs.open()` as that's only necessary for keeping compatibility with Python 2.5.

The constructors of both `str` and `bytes` have different semantics for the same arguments between Python 2 and 3. Passing an integer to `bytes` in Python 2 will give you the string representation of the integer: `bytes(3) == '3'`. But in Python 3, an integer argument to `bytes` will give you a bytes object as long as the integer specified, filled with null bytes: `bytes(3) == b'\x00\x00\x00'`. A similar worry is necessary when passing a bytes object to `str`. In Python 2 you just get the bytes object back: `str(b'3') == b'3'`. But in Python 3 you get the string representation of the bytes object: `str(b'3') == "b'3'"`.

Finally, the indexing of binary data requires careful handling (slicing does **not** require any special handling). In Python 2, `b'123'[1] == b'2'` while in Python 3 `b'123'[1] == 50`. Because binary data is simply a collection of binary numbers, Python 3 returns the integer value for the byte you index on. But in Python 2 because `bytes == str`, indexing returns a one-item slice of bytes. The [six](https://pypi.org/project/six) [https://pypi.org/project/six] project has a function named `six.indexbytes()` which will return an integer like in Python 3: `six.indexbytes(b'123', 1)`.

To summarize:

1. Decide which of your APIs take text and which take binary data
2. Make sure that your code that works with text also works with `unicode` and code for binary data works with `bytes` in Python 2 (see the table above for what methods you cannot

- use for each type)
- 3. Mark all binary literals with a `b` prefix, textual literals with a `u` prefix
- 4. Decode binary data to text as soon as possible, encode text as binary data as late as possible
- 5. Open files using `io.open()` and make sure to specify the `b` mode when appropriate
- 6. Be careful when indexing into binary data

## Use feature detection instead of version detection

Inevitably you will have code that has to choose what to do based on what version of Python is running. The best way to do this is with feature detection of whether the version of Python you're running under supports what you need. If for some reason that doesn't work then you should make the version check be against Python 2 and not Python 3. To help explain this, let's look at an example.

Let's pretend that you need access to a feature of `importlib` that is available in Python's standard library since Python 3.3 and available for Python 2 through `importlib2` [<https://pypi.org/project/importlib2>] on PyPI. You might be tempted to write code to access e.g. the `importlib.abc` module by doing the following:

```
import sys

if sys.version_info[0] == 3:
    from importlib import abc
else:
    from importlib2 import abc
```

The problem with this code is what happens when Python 4 comes out? It would be better to treat Python 2 as the exceptional case instead of Python 3 and assume that future Python versions will be more compatible with Python 3 than Python 2:

```
import sys

if sys.version_info[0] > 2:
```

```
    from importlib import abc
else:
    from importlib2 import abc
```

The best solution, though, is to do no version detection at all and instead rely on feature detection. That avoids any potential issues of getting the version detection wrong and helps keep you future-compatible:

```
try:
    from importlib import abc
except ImportError:
    from importlib2 import abc
```

## Prevent compatibility regressions

Once you have fully translated your code to be compatible with Python 3, you will want to make sure your code doesn't regress and stop working under Python 3. This is especially true if you have a dependency which is blocking you from actually running under Python 3 at the moment.

To help with staying compatible, any new modules you create should have at least the following block of code at the top of it:

```
from __future__ import absolute_import
from __future__ import division
from __future__ import print_function
```

You can also run Python 2 with the `-3` flag to be warned about various compatibility issues your code triggers during execution. If you turn warnings into errors with `-Werror` then you can make sure that you don't accidentally miss a warning.

You can also use the [Pylint](https://pypi.org/project/pylint) [https://pypi.org/project/pylint] project and its `--py3k` flag to lint your code to receive warnings when your code begins to deviate from Python 3 compatibility. This also prevents you from having to run [Modernize](https://python-modernize.readthedocs.io/) [https://python-modernize.readthedocs.io/] or [Futurize](https://python-future.org/automatic_conversion.html) [https://python-future.org/automatic\_conversion.html] over your code regularly to catch

compatibility regressions. This does require you only support Python 2.7 and Python 3.4 or newer as that is Pylint's minimum Python version support.

## Check which dependencies block your transition

**After** you have made your code compatible with Python 3 you should begin to care about whether your dependencies have also been ported. The [caniusepython3](https://pypi.org/project/caniusepython3) [https://pypi.org/project/caniusepython3] project was created to help you determine which projects – directly or indirectly – are blocking you from supporting Python 3. There is both a command-line tool as well as a web interface at <https://caniusepython3.com>.

The project also provides code which you can integrate into your test suite so that you will have a failing test when you no longer have dependencies blocking you from using Python 3. This allows you to avoid having to manually check your dependencies and to be notified quickly when you can start running on Python 3.

## Update your `setup.py` file to denote Python 3 compatibility

Once your code works under Python 3, you should update the classifiers in your `setup.py` to contain `Programming Language :: Python :: 3` and to not specify sole Python 2 support. This will tell anyone using your code that you support Python 2 and 3. Ideally you will also want to add classifiers for each major/minor version of Python you now support.

## Use continuous integration to stay compatible

Once you are able to fully run under Python 3 you will want to make sure your code always works under both Python 2 and 3. Probably the best tool for running your tests under multiple Python interpreters is [tox](https://pypi.org/project/tox) [https://pypi.org/project/tox]. You can then integrate tox with your continuous integration system so that you never accidentally break Python 2 or 3 support.

You may also want to use the `-bb` flag with the Python 3

interpreter to trigger an exception when you are comparing bytes to strings or bytes to an int (the latter is available starting in Python 3.5). By default type-differing comparisons simply return `False`, but if you made a mistake in your separation of text/binary data handling or indexing on bytes you wouldn't easily find the mistake. This flag will raise an exception when these kinds of comparisons occur, making the mistake much easier to track down.

## Consider using optional static type checking

Another way to help port your code is to use a static type checker like [mypy](https://mypy-lang.org/) [https://mypy-lang.org/] or [pytype](https://github.com/google/pytype) [https://github.com/google/pytype] on your code. These tools can be used to analyze your code as if it's being run under Python 2, then you can run the tool a second time as if your code is running under Python 3. By running a static type checker twice like this you can discover if you're e.g. misusing binary data type in one version of Python compared to another. If you add optional type hints to your code you can also explicitly state whether your APIs use textual or binary data, helping to make sure everything functions as expected in both versions of Python.

# Porting Extension Modules to Python 3

We recommend the following resources for porting extension modules to Python 3:

- The [Migrating C extensions](http://python3porting.com/cextensions.html) [http://python3porting.com/cextensions.html] chapter from *Supporting Python 3: An in-depth guide*, a book on moving from Python 2 to Python 3 in general, guides the reader through porting an extension module.
- The [Porting guide](https://py3c.readthedocs.io/en/latest/guide.html) [https://py3c.readthedocs.io/en/latest/guide.html] from the *py3c* project provides opinionated suggestions with supporting code.
- The [Cython](https://cython.org/) [https://cython.org/] and [CFFI](https://cffi.readthedocs.io/en/latest/) [https://cffi.readthedocs.io/en/latest/] libraries offer abstractions over Python's C API. Extensions generally need to be re-written to use one of them, but the library then handles differences between various Python versions and implementations.

# Curses Programming with Python

**Author**

A.M. Kuchling, Eric S. Raymond

**Release**

2.04

## Abstract

This document describes how to use the `curses` extension module to control text-mode displays.

## What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by various programs. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of graphical displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One niche is on small-footprint or embedded Unixes that don’t run an X server. Another is tools such as OS installers and kernel configurators that may have to run before any graphical support is available.

The curses library provides fairly basic functionality, providing the programmer with an abstraction of a display containing multiple

non-overlapping windows of text. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will figure out what control codes need to be sent to the terminal to produce the right output. curses doesn't provide many user-interface concepts such as buttons, checkboxes, or dialogs; if you need such features, consider a user interface library such as [Urwid](https://pypi.org/project/urwid/) [https://pypi.org/project/urwid/].

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T interface. If you're using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older versions of curses carried by some proprietary Unixes may not support everything, though.

The Windows version of Python doesn't include the `curses` module. A ported version called [UniCurses](https://pypi.org/project/UniCurses) [https://pypi.org/project/UniCurses] is available.

## The Python curses module

The Python module is a fairly simple wrapper over the C functions provided by curses; if you're already familiar with curses programming in C, it's really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler by merging different C functions such as `addstr()`, `mvaddstr()`, and `mvwaddstr()` into a single `addstr()` method. You'll see this covered in more detail later.

This HOWTO is an introduction to writing text-mode programs with curses and Python. It doesn't attempt to be a complete guide to the curses API; for that, see the Python library guide's section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.

## Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the `initscr()` function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, `initscr()` returns a window object representing the entire screen; this is usually called `stdscr` after the name of the corresponding C variable.

```
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the `noecho()` function.

```
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you'll have to enable keypad mode.

```
stdscr.keypad(True)
```

Terminating a curses application is much easier than starting one. You'll need to call:

```
curses.nocbreak()
stdscr.keypad(False)
curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the

`endwin()` function to restore the terminal to its original operating mode.

```
curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the `curses.wrapper()` function and using it like this:

```
from curses import wrapper

def main(stdscr):
    # Clear screen
    stdscr.clear()

    # This raises ZeroDivisionError when i == 10.
    for i in range(0, 11):
        v = i-10
        stdscr.addstr(i, 0, '10 divided by {} is {}'.format(i, v))

    stdscr.refresh()
    stdscr.getkey()

wrapper(main)
```

The `wrapper()` function takes a callable object and does the initializations described above, also initializing colors if color support is present. `wrapper()` then runs your provided callable. Once the callable returns, `wrapper()` will restore the original state of the terminal. The callable is called inside a `try...except` that catches exceptions, restores the state of the terminal, and then re-raises the exception. Therefore your terminal won't be left in a funny state on exception and you'll be able to read the exception's

message and traceback.

## Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```
begin_x = 20; begin_y = 7
height = 5; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

Note that the coordinate system used in curses is unusual. Coordinates are always passed in the order *y,x*, and the top-left corner of a window is coordinate (0,0). This breaks the normal convention for handling coordinates where the *x* coordinate comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

Your application can determine the size of the screen by using the `curses.LINES` and `curses.COLS` variables to obtain the *y* and *x* sizes. Legal coordinates will then extend from (0,0) to (curses.LINES - 1, curses.COLS - 1).

When you call a method to display or erase text, the effect doesn't immediately show up on the display. Instead you must call the `refresh()` method of window objects to update the screen.

This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen was very important. Instead curses accumulates changes to the screen and displays them in the

most efficient manner when you call **refresh()**. For example, if your program displays some text in a window and then clears the window, there's no need to send the original text because they're never visible.

In practice, explicitly telling curses to redraw a window doesn't really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by first calling **stdscr.refresh()** or the **refresh()** method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of the pad displayed at a time. Creating a pad requires the pad's height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```
pad = curses.newpad(100, 100)
# These loops fill the pad with letters; addch() is
# explained in the next section
for y in range(0, 99):
    for x in range(0, 99):
        pad.addch(y,x, ord('a') + (x*x+y*y) % 26)

# Displays a section of the pad in the middle of the screen
# (0,0) : coordinate of upper-left corner of pad area to be
# (5,5) : coordinate of upper-left corner of window area to
#         with pad content.
# (20, 75) : coordinate of lower-right corner of window area
#           : filled with pad content.
pad.refresh( 0,0, 5,5, 20,75)
```

The **refresh()** call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to update the screen and prevent annoying screen flicker as each part of the screen gets updated. **refresh()** actually does two things:

1. Calls the **noutrefresh()** method of each window to update an underlying data structure representing the desired state of the screen.
2. Calls the function **doupdate()** function to change the physical screen to match the desired state recorded in the data structure.

Instead you can call **noutrefresh()** on a number of windows to update the data structure, and then call **doupdate()** to update the screen.

## Displaying Text

From a C programmer's point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, **addstr()** displays a string at the current cursor location in the `stdscr` window, while **mvaddstr()** moves to a given y,x coordinate first before displaying the string. **waddstr()** is just like **addstr()**, but allows specifying a window to use instead of using `stdscr` by default. **mvwaddstr()** allows specifying both a window and a coordinate.

Fortunately the Python interface hides all these details. `stdscr` is a window object like any other, and methods such as **addstr()** accept multiple argument forms. Usually there are four different forms.

### Description

---

**Display** the string *str* or character *ch* at the current position

---

**Display** the string *str* or character *ch*, using attribute *attr* at the current position

---

**Move to position** y,x within the window, and display *str* or *ch*

---

**Move to position** y,x within the window, and display *str* or *ch*, using attribute *attr*

---

Attributes allow displaying text in highlighted forms such as boldface, underline, reverse code, or in color. They'll be explained in more detail in the next subsection.

The `addstr()` method takes a Python string or bytestring as the value to be displayed. The contents of bytestrings are sent to the terminal as-is. Strings are encoded to bytes using the value of the window's `encoding` attribute; this defaults to the default system encoding as returned by `locale.getencoding()`.

The `addch()` methods take a character, which can be either a string of length 1, a bytestring of length 1, or an integer.

Constants are provided for extension characters; these constants are integers greater than 255. For example, `ACS_PLMINUS` is a `+/-` symbol, and `ACS_ULCORNER` is the upper left corner of a box (handy for drawing borders). You can also use the appropriate Unicode character.

Windows remember where the cursor was left after the last operation, so if you leave out the `y,x` coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y, x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won't be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn't need a blinking cursor at all, you can call `curs_set(False)` to make it invisible. For compatibility with older curses versions, there's a `leaveok(bool)` function that's a synonym for `curs_set()`. When `bool` is true, the curses library will attempt to suppress the flashing cursor, and you won't need to worry about leaving it in odd locations.

## Attributes and Color

Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video, or a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is an integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn't guarantee that all the possible combinations are available, or that they're all visually distinct. That depends on the ability of the terminal being used, so it's safest to stick to the most commonly available attributes, listed here.

Description
<u>Blinking</u> text
<u>Extra bright</u> or bold text
<u>Half bright</u> text
<u>Reverse video</u> text
<u>The best</u> highlighting mode available
<u>Underlined</u> text

So, to display a reverse-video status line on the top line of the screen, you could code:

```
stdscr.addstr(0, 0, "Current mode: Typing mode",
               curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.

To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper()` function does this automatically). Once that's done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: curses uses the American spelling 'color', instead of the Canadian/British spelling 'colour'. If you're used to the British spelling, you'll have to resign yourself to misspelling it for the sake of these functions.)

The curses library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR'ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work on all terminals.

An example, which displays a line of text using color pair 1:

```
stdscr.addstr("Pretty text", curses.color_pair(1))
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. The `init_pair(n, f, b)` function changes the definition of color pair *n*, to foreground color *f* and background color *b*. Color pair 0 is hard-wired to white on black, and cannot be changed.

Colors are numbered, and `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The `curses` module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

Let's put all this together. To change color 1 to red text on a white background, you would call:

```
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```
stdscr.addstr(0,0, "RED ALERT!", curses.color_pair(1))
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn't support this, so I'm unable to try it out, and can't provide any examples. You can check if your terminal can do this by calling `can_change_color()`, which returns `True` if the capability is there. If you're lucky enough to have such a talented terminal, consult your system's man pages for more information.

## User Input

The C `curses` library offers only very simple input mechanisms.

Python's `curses` module adds a basic text-input widget. (Other libraries such as `Urwid` [<https://pypi.org/project/urwid/>] have more extensive collections of widgets.)

There are two methods for getting input from a window:

- `getch()` refreshes the screen and then waits for the user to hit a key, displaying the key if `echo()` has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.
- `getkey()` does the same thing but converts the integer to a string. Individual characters are returned as 1-character strings, and special keys such as function keys return longer strings containing a key name such as `KEY_UP` or `^G`.

It's possible to not wait for the user using the `nodelay()` window method. After `nodelay(True)`, `getch()` and `getkey()` for the window become non-blocking. To signal that no input is ready, `getch()` returns `curses.ERR` (a value of -1) and `getkey()` raises an exception. There's also a `halfdelay()` function, which can be used to (in effect) set a timer on each `getch()`; if no input becomes available within a specified delay (measured in tenths of a second), `curses` raises an exception.

The `getch()` method returns an integer; if it's between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as `curses.KEY_PPAGE`, `curses.KEY_HOME`, or `curses.KEY_LEFT`. The main loop of your program may look something like this:

```
while True:
    c = stdscr.getch()
    if c == ord('p'):
        PrintDocument()
    elif c == ord('q'):
        break # Exit the while loop
    elif c == curses.KEY_HOME:
        x = y = 0
```

The `curses.ascii` module supplies ASCII class membership functions that take either integer or 1-character string arguments; these may be useful in writing more readable tests for such loops. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, `curses.ascii.ctrl()` returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, `getstr()`. It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

```
curses.echo()                # Enable echoing of characters

# Get a 15-character string, with the cursor on the top
s = stdscr.getstr(0,0, 15)
```

The `curses.textpad` module supplies a text box that supports an Emacs-like set of keybindings. Various methods of the `Textbox` class support editing with input validation and gathering the edit results either with or without trailing spaces. Here's an example:

```
import curses
from curses.textpad import Textbox, rectangle

def main(stdscr):
    stdscr.addstr(0, 0, "Enter IM message: (hit Ctrl-G t

    editwin = curses.newwin(5,30, 2,1)
    rectangle(stdscr, 1,0, 1+5+1, 1+30+1)
    stdscr.refresh()

    box = Textbox(editwin)

    # Let the user edit until Ctrl-G is struck.
    box.edit()

    # Get resulting contents
```

```
message = box.gather()
```

See the library documentation on [curses.textpad](#) for more details.

## For More Information

This HOWTO doesn't cover some advanced topics, such as reading the contents of the screen or capturing mouse events from an xterm instance, but the Python library page for the [curses](#) module is now reasonably complete. You should browse it next.

If you're in doubt about the detailed behavior of the curses functions, consult the manual pages for your curses implementation, whether it's ncurses or a proprietary Unix vendor's. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and [ACS\\_\\*](#) characters available to you.

Because the curses API is so large, some functions aren't supported in the Python interface. Often this isn't because they're difficult to implement, but because no one has needed them yet. Also, Python doesn't yet support the menu library associated with ncurses. Patches adding support for these would be welcome; see [the Python Developer's Guide](#) [<https://devguide.python.org/>] to learn more about submitting patches to Python.

**Descriptors** let objects customize attribute lookup, storage, and deletion.

This guide has four major sections:

1. The “primer” gives a basic overview, moving gently from simple examples, adding one feature at a time. Start here if you’re new to descriptors.
2. The second section shows a complete, practical descriptor example. If you already know the basics, start there.
3. The third section provides a more technical tutorial that goes into the detailed mechanics of how descriptors work. Most people don’t need this level of detail.
4. The last section has pure Python equivalents for built-in descriptors that are written in C. Read this if you’re curious about how functions turn into bound methods or about the implementation of common tools like `classmethod()`, `staticmethod()`, `property()`, and `__slots__`.

## Primer

In this primer, we start with the most basic possible example and then we’ll add new capabilities one by one.

### Simple example: A descriptor that returns a constant

The `Ten` class is a descriptor whose `__get__()` method always returns the constant `10`:

```
class Ten:
    def __get__(self, obj, objtype=None):
        return 10
```

To use the descriptor, it must be stored as a class variable in another class:

```
class A:
    x = 5                                # Regular class attribute
    y = Ten()                           # Descriptor instance
```

An interactive session shows the difference between normal attribute lookup and descriptor lookup:

```
>>> a = A()                            # Make an instance of class A
>>> a.x                                # Normal attribute lookup
5
>>> a.y                                # Descriptor lookup
10
```

In the `a.x` attribute lookup, the dot operator finds `'x': 5` in the class dictionary. In the `a.y` lookup, the dot operator finds a descriptor instance, recognized by its `__get__` method. Calling that method returns `10`.

Note that the value `10` is not stored in either the class dictionary or the instance dictionary. Instead, the value `10` is computed on demand.

This example shows how a simple descriptor works, but it isn't very useful. For retrieving constants, normal attribute lookup would be better.

In the next section, we'll create something more useful, a dynamic lookup.

## Dynamic lookups

Interesting descriptors typically run computations instead of returning constants:

```
import os

class DirectorySize:

    def __get__(self, obj, objtype=None):
        return len(os.listdir(obj.dirname))
```

```

class Directory:

    size = DirectorySize()                # Descriptor instance

    def __init__(self, dirname):
        self.dirname = dirname            # Regular instance attribute

```

An interactive session shows that the lookup is dynamic — it computes different, updated answers each time:

```

>>> s = Directory('songs')
>>> g = Directory('games')
>>> s.size                                # The songs directory
20
>>> g.size                                # The games directory
3
>>> os.remove('games/chess')              # Delete a game
>>> g.size                                # File count is
2

```

Besides showing how descriptors can run computations, this example also reveals the purpose of the parameters to `__get__()`. The *self* parameter is *size*, an instance of *DirectorySize*. The *obj* parameter is either *g* or *s*, an instance of *Directory*. It is the *obj* parameter that lets the `__get__()` method learn the target directory. The *objtype* parameter is the class *Directory*.

## Managed attributes

A popular use for descriptors is managing access to instance data. The descriptor is assigned to a public attribute in the class dictionary while the actual data is stored as a private attribute in the instance dictionary. The descriptor's `__get__()` and `__set__()` methods are triggered when the public attribute is accessed.

In the following example, *age* is the public attribute and *\_age* is the private attribute. When the public attribute is accessed, the descriptor logs the lookup or update:

```

import logging

logging.basicConfig(level=logging.INFO)

class LoggedAgeAccess:

    def __get__(self, obj, objtype=None):
        value = obj._age
        logging.info('Accessing %r giving %r', 'age', value)
        return value

    def __set__(self, obj, value):
        logging.info('Updating %r to %r', 'age', value)
        obj._age = value

class Person:

    age = LoggedAgeAccess()  # Descriptor instance

    def __init__(self, name, age):
        self.name = name    # Regular instance attribute
        self.age = age      # Calls __set__()

    def birthday(self):
        self.age += 1       # Calls both __get__() and __set__()

```

An interactive session shows that all access to the managed attribute *age* is logged, but that the regular attribute *name* is not logged:

```

>>> mary = Person('Mary M', 30)  # The initial age is 30
INFO:root:Updating 'age' to 30
>>> dave = Person('David D', 40)
INFO:root:Updating 'age' to 40

>>> vars(mary)  # The actual data dictionary
{'name': 'Mary M', '_age': 30}
>>> vars(dave)
{'name': 'David D', '_age': 40}

```

```

>>> mary.age                                     # Access the data
INFO:root:Accessing 'age' giving 30
30
>>> mary.birthday()                             # Updates are local
INFO:root:Accessing 'age' giving 30
INFO:root:Updating 'age' to 31

>>> dave.name                                    # Regular attribute
'David D'
>>> dave.age                                     # Only the managed
INFO:root:Accessing 'age' giving 40
40

```

One major issue with this example is that the private name `_age` is hardwired in the `LoggedAgeAccess` class. That means that each instance can only have one logged attribute and that its name is unchangeable. In the next example, we'll fix that problem.

## Customized names

When a class uses descriptors, it can inform each descriptor about which variable name was used.

In this example, the **Person** class has two descriptor instances, *name* and *age*. When the **Person** class is defined, it makes a callback to `__set_name__()` in `LoggedAccess` so that the field names can be recorded, giving each descriptor its own *public\_name* and *private\_name*:

```

import logging

logging.basicConfig(level=logging.INFO)

class LoggedAccess:

    def __set_name__(self, owner, name):
        self.public_name = name
        self.private_name = '_' + name

```

```

def __get__(self, obj, objtype=None):
    value = getattr(obj, self.private_name)
    logging.info('Accessing %r giving %r', self.public_name, value)
    return value

def __set__(self, obj, value):
    logging.info('Updating %r to %r', self.public_name, value)
    setattr(obj, self.private_name, value)

```

```
class Person:
```

```

    name = LoggedAccess()           # First descriptor
    age = LoggedAccess()            # Second descriptor

    def __init__(self, name, age):
        self.name = name            # Calls the first descriptor
        self.age = age              # Calls the second descriptor

    def birthday(self):
        self.age += 1

```

An interactive session shows that the **Person** class has called **\_\_set\_name\_\_()** so that the field names would be recorded. Here we call **vars()** to look up the descriptor without triggering it:

```

>>> vars(vars(Person)['name'])
{'public_name': 'name', 'private_name': '_name'}
>>> vars(vars(Person)['age'])
{'public_name': 'age', 'private_name': '_age'}

```

The new class now logs access to both *name* and *age*:

```

>>> pete = Person('Peter P', 10)
INFO:root:Updating 'name' to 'Peter P'
INFO:root:Updating 'age' to 10
>>> kate = Person('Catherine C', 20)
INFO:root:Updating 'name' to 'Catherine C'
INFO:root:Updating 'age' to 20

```

The two *Person* instances contain only the private names:

```
>>> vars(pete)
{'_name': 'Peter P', '_age': 10}
>>> vars(kate)
{'_name': 'Catherine C', '_age': 20}
```

## Closing thoughts

A [descriptor](#) is what we call any object that defines `__get__()`, `__set__()`, or `__delete__()`.

Optionally, descriptors can have a `__set_name__()` method. This is only used in cases where a descriptor needs to know either the class where it was created or the name of class variable it was assigned to. (This method, if present, is called even if the class is not a descriptor.)

Descriptors get invoked by the dot operator during attribute lookup. If a descriptor is accessed indirectly with `vars(some_class)[descriptor_name]`, the descriptor instance is returned without invoking it.

Descriptors only work when used as class variables. When put in instances, they have no effect.

The main motivation for descriptors is to provide a hook allowing objects stored in class variables to control what happens during attribute lookup.

Traditionally, the calling class controls what happens during lookup. Descriptors invert that relationship and allow the data being looked-up to have a say in the matter.

Descriptors are used throughout the language. It is how functions turn into bound methods. Common tools like [classmethod\(\)](#), [staticmethod\(\)](#), [property\(\)](#), and [functools.cached\\_property\(\)](#) are all implemented as descriptors.

# Complete Practical Example

In this example, we create a practical and powerful tool for locating notoriously hard to find data corruption bugs.

## Validator class

A validator is a descriptor for managed attribute access. Prior to storing any data, it verifies that the new value meets various type and range restrictions. If those restrictions aren't met, it raises an exception to prevent data corruption at its source.

This **Validator** class is both an [abstract base class](#) and a managed attribute descriptor:

```
from abc import ABC, abstractmethod

class Validator(ABC):

    def __set_name__(self, owner, name):
        self.private_name = '_' + name

    def __get__(self, obj, objtype=None):
        return getattr(obj, self.private_name)

    def __set__(self, obj, value):
        self.validate(value)
        setattr(obj, self.private_name, value)

    @abstractmethod
    def validate(self, value):
        pass
```

Custom validators need to inherit from **Validator** and must supply a **validate()** method to test various restrictions as needed.

## Custom validators

Here are three practical data validation utilities:

1. **OneOf** verifies that a value is one of a restricted set of options.
2. **Number** verifies that a value is either an **int** or **float**. Optionally, it verifies that a value is between a given minimum or maximum.
3. **String** verifies that a value is a **str**. Optionally, it validates a given minimum or maximum length. It can validate a user-defined **predicate** [[https://en.wikipedia.org/wiki/Predicate\\_\(mathematical\\_logic\)](https://en.wikipedia.org/wiki/Predicate_(mathematical_logic))] as well.

```
class OneOf(Validator):
```

```
    def __init__(self, *options):
        self.options = set(options)

    def validate(self, value):
        if value not in self.options:
            raise ValueError(f'Expected {value!r} to be
```

```
class Number(Validator):
```

```
    def __init__(self, minvalue=None, maxvalue=None):
        self.minvalue = minvalue
        self.maxvalue = maxvalue

    def validate(self, value):
        if not isinstance(value, (int, float)):
            raise TypeError(f'Expected {value!r} to be a
        if self.minvalue is not None and value < self.mi
            raise ValueError(
                f'Expected {value!r} to be at least {sel
            )
        if self.maxvalue is not None and value > self.ma
            raise ValueError(
                f'Expected {value!r} to be no more than
            )
```

```

class String(Validator):

    def __init__(self, minsize=None, maxsize=None, predicate=None):
        self.minsize = minsize
        self.maxsize = maxsize
        self.predicate = predicate

    def validate(self, value):
        if not isinstance(value, str):
            raise TypeError(f'Expected {value!r} to be a string')
        if self.minsize is not None and len(value) < self.minsize:
            raise ValueError(
                f'Expected {value!r} to be no smaller than {self.minsize}'
            )
        if self.maxsize is not None and len(value) > self.maxsize:
            raise ValueError(
                f'Expected {value!r} to be no bigger than {self.maxsize}'
            )
        if self.predicate is not None and not self.predicate(value):
            raise ValueError(
                f'Expected {self.predicate} to be true for {value!r}'
            )

```

## Practical application

Here's how the data validators can be used in a real class:

```

class Component:

    name = String(minsize=3, maxsize=10, predicate=str.isalpha)
    kind = OneOf('wood', 'metal', 'plastic')
    quantity = Number(minvalue=0)

    def __init__(self, name, kind, quantity):
        self.name = name
        self.kind = kind
        self.quantity = quantity

```

The descriptors prevent invalid instances from being created:

```
>>> Component('Widget', 'metal', 5)          # Blocked: 'Wid
Traceback (most recent call last):
...
ValueError: Expected <method 'isupper' of 'str' objects>

>>> Component('WIDGET', 'metle', 5)          # Blocked: 'met
Traceback (most recent call last):
...
ValueError: Expected 'metle' to be one of {'metal', 'pla

>>> Component('WIDGET', 'metal', -5)         # Blocked: -5 i
Traceback (most recent call last):
...
ValueError: Expected -5 to be at least 0
>>> Component('WIDGET', 'metal', 'V')       # Blocked: 'V'
Traceback (most recent call last):
...
TypeError: Expected 'V' to be an int or float

>>> c = Component('WIDGET', 'metal', 5)     # Allowed: The
```

## Technical Tutorial

What follows is a more technical tutorial for the mechanics and details of how descriptors work.

### Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Provides an example showing how object relational mappings work.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works.

### Definition and introduction

In general, a descriptor is an attribute value that has one of the

methods in the descriptor protocol. Those methods are `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an attribute, it is said to be a [descriptor](#).

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the method resolution order of `type(a)`. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined.

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and [super\(\)](#). They are used throughout Python itself. Descriptors simplify the underlying C code and offer a flexible set of new tools for everyday Python programs.

## Descriptor protocol

```
descr.__get__(self, obj, type=None) -> value
```

```
descr.__set__(self, obj, value) -> None
```

```
descr.__delete__(self, obj) -> None
```

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines `__set__()` or `__delete__()`, it is considered a data descriptor. Descriptors that only define `__get__()` are called non-data descriptors (they are often used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance's dictionary. If an instance's dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance's dictionary has

an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both `__get__()` and `__set__()` with the `__set__()` raising an `AttributeError` when called. Defining the `__set__()` method with an exception raising placeholder is enough to make it a data descriptor.

## Overview of descriptor invocation

A descriptor can be called directly with `desc.__get__(obj)` or `desc.__get__(None, cls)`.

But it is more common for a descriptor to be invoked automatically from attribute access.

The expression `obj.x` looks up the attribute `x` in the chain of namespaces for `obj`. If the search finds a descriptor outside of the instance `__dict__`, its `__get__()` method is invoked according to the precedence rules listed below.

The details of invocation depend on whether `obj` is an object, class, or instance of super.

## Invocation from an instance

Instance lookup scans through a chain of namespaces giving data descriptors the highest priority, followed by instance variables, then non-data descriptors, then class variables, and lastly `__getattr__()` if it is provided.

If a descriptor is found for `a.x`, then it is invoked with:  
`desc.__get__(a, type(a))`.

The logic for a dotted lookup is in `object.__getattribute__()`. Here is a pure Python equivalent:

```
def find_name_in_mro(cls, name, default):
    "Emulate _PyType_Lookup() in Objects/typeobject.c"
    for base in cls.__mro__:
```

```

        if name in vars(base):
            return vars(base)[name]
        return default

def object_getattribute(obj, name):
    "Emulate PyObject_GenericGetAttr() in Objects/object.c"
    null = object()
    objtype = type(obj)
    cls_var = find_name_in_mro(objtype, name, null)
    descr_get = getattr(type(cls_var), '__get__', null)
    if descr_get is not null:
        if (hasattr(type(cls_var), '__set__')
            or hasattr(type(cls_var), '__delete__')):
            return descr_get(cls_var, obj, objtype)
    if hasattr(obj, '__dict__') and name in vars(obj):
        return vars(obj)[name]
    if descr_get is not null:
        return descr_get(cls_var, obj, objtype)
    if cls_var is not null:
        return cls_var
    raise AttributeError(name)

```

Note, there is no `__getattr__()` hook in the `__getattribute__()` code. That is why calling `__getattribute__()` directly or with `super().__getattribute__` will bypass `__getattr__()` entirely.

Instead, it is the dot operator and the `getattr()` function that are responsible for invoking `__getattr__()` whenever `__getattribute__()` raises an `AttributeError`. Their logic is encapsulated in a helper function:

```

def getattr_hook(obj, name):
    "Emulate slot_tp_getattr_hook() in Objects/typeobject.c"
    try:
        return obj.__getattribute__(name)
    except AttributeError:
        if not hasattr(type(obj), '__getattr__'):

```

```
        raise
    return type(obj).__getattr__(obj, name)
```

## Invocation from a class

The logic for a dotted lookup such as `A.x` is in `type.__getattribute__()`. The steps are similar to those for `object.__getattribute__()` but the instance dictionary lookup is replaced by a search through the class's [method resolution order](#).

If a descriptor is found, it is invoked with `desc.__get__(None, A)`.

The full C implementation can be found in `type_getattro()` and `_PyType_Lookup()` in [Objects/typeobject.c](#) [<https://github.com/python/cpython/tree/3.12/Objects/typeobject.c>].

## Invocation from super

The logic for super's dotted lookup is in the `__getattribute__()` method for object returned by `super()`.

A dotted lookup such as `super(A, obj).m` searches `obj.__class__.__mro__` for the base class `B` immediately following `A` and then returns `B.__dict__['m'].__get__(obj, A)`. If not a descriptor, `m` is returned unchanged.

The full C implementation can be found in `super_getattro()` in [Objects/typeobject.c](#) [<https://github.com/python/cpython/tree/3.12/Objects/typeobject.c>]. A pure Python equivalent can be found in [Guido's Tutorial](#) [<https://www.python.org/download/releases/2.2.3/descrintro/#cooperation>].

## Summary of invocation logic

The mechanism for descriptors is embedded in the `__getattribute__()` methods for [object](#), [type](#), and [super\(\)](#).

The important points to remember are:

- Descriptors are invoked by the `__getattr__()` method.
- Classes inherit this machinery from `object`, `type`, or `super()`.
- Overriding `__getattr__()` prevents automatic descriptor calls because all the descriptor logic is in that method.
- `object.__getattr__()` and `type.__getattr__()` make different calls to `__get__()`. The first includes the instance and may include the class. The second puts in `None` for the instance and always includes the class.
- Data descriptors always override instance dictionaries.
- Non-data descriptors may be overridden by instance dictionaries.

## Automatic name notification

Sometimes it is desirable for a descriptor to know what class variable name it was assigned to. When a new class is created, the `type` metaclass scans the dictionary of the new class. If any of the entries are descriptors and if they define `__set_name__()`, that method is called with two arguments. The *owner* is the class where the descriptor is used, and the *name* is the class variable the descriptor was assigned to.

The implementation details are in `type_new()` and `set_names()` in [Objects/typeobject.c](https://github.com/python/cpython/tree/3.12/Objects/typeobject.c) [https://github.com/python/cpython/tree/3.12/Objects/typeobject.c].

Since the update logic is in `type.__new__()`, notifications only take place at the time of class creation. If descriptors are added to the class afterwards, `__set_name__()` will need to be called manually.

## ORM example

The following code is a simplified skeleton showing how data

descriptors could be used to implement an [object relational mapping](https://en.wikipedia.org/wiki/Object%E2%80%93relational_mapping) [https://en.wikipedia.org/wiki/Object%E2%80%93relational\_mapping].

The essential idea is that the data is stored in an external database. The Python instances only hold keys to the database's tables. Descriptors take care of lookups or updates:

```
class Field:

    def __set_name__(self, owner, name):
        self.fetch = f'SELECT {name} FROM {owner.table}'
        self.store = f'UPDATE {owner.table} SET {name}=?'

    def __get__(self, obj, objtype=None):
        return conn.execute(self.fetch, [obj.key]).fetchone()

    def __set__(self, obj, value):
        conn.execute(self.store, [value, obj.key])
        conn.commit()
```

We can use the **Field** class to define [models](https://en.wikipedia.org/wiki/Database_model) [https://en.wikipedia.org/wiki/Database\_model] that describe the schema for each table in a database:

```
class Movie:
    table = 'Movies'                # Table name
    key = 'title'                   # Primary key
    director = Field()
    year = Field()

    def __init__(self, key):
        self.key = key

class Song:
    table = 'Music'
    key = 'title'
    artist = Field()
    year = Field()
    genre = Field()
```

```
def __init__(self, key):
    self.key = key
```

To use the models, first connect to the database:

```
>>> import sqlite3
>>> conn = sqlite3.connect('entertainment.db')
```

An interactive session shows how data is retrieved from the database and how it can be updated:

```
>>> Movie('Star Wars').director
'George Lucas'
>>> jaws = Movie('Jaws')
>>> f'Released in {jaws.year} by {jaws.director}'
'Released in 1975 by Steven Spielberg'

>>> Song('Country Roads').artist
'John Denver'

>>> Movie('Star Wars').director = 'J.J. Abrams'
>>> Movie('Star Wars').director
'J.J. Abrams'
```

## Pure Python Equivalents

The descriptor protocol is simple and offers exciting possibilities. Several use cases are so common that they have been prepackaged into built-in tools. Properties, bound methods, static methods, class methods, and `__slots__` are all based on the descriptor protocol.

### Properties

Calling `property()` is a succinct way of building a data descriptor that triggers a function call upon access to an attribute. Its signature is:

```
property(fget=None, fset=None, fdel=None, doc=None) -> p
```

The documentation shows a typical use to define a managed attribute `x`:

```
class C:
    def getx(self): return self.__x
    def setx(self, value): self.__x = value
    def delx(self): del self.__x
    x = property(getx, setx, delx, "I'm the 'x' property")
```

To see how `property()` is implemented in terms of the descriptor protocol, here is a pure Python equivalent:

```
class Property:
    "Emulate PyProperty_Type() in Objects/descrobject.c"

    def __init__(self, fget=None, fset=None, fdel=None,
                 self.fget = fget
                 self.fset = fset
                 self.fdel = fdel
                 if doc is None and fget is not None:
                     doc = fget.__doc__
                 self.__doc__ = doc
                 self._name = ''

    def __set_name__(self, owner, name):
        self._name = name

    def __get__(self, obj, objtype=None):
        if obj is None:
            return self
        if self.fget is None:
            raise AttributeError(f"property '{self._name}' of '{objtype}' object has no attribute '{self._name}'")
        return self.fget(obj)

    def __set__(self, obj, value):
        if self.fset is None:
            raise AttributeError(f"property '{self._name}' of '{objtype}' object is read-only")
        self.fset(obj, value)
```

```

def __delete__(self, obj):
    if self.fdel is None:
        raise AttributeError(f"property '{self._name}' of {self.fdel(obj)} object has no attribute '{self._name}'")

def getter(self, fget):
    prop = type(self)(fget, self.fset, self.fdel, self._name)
    return prop

def setter(self, fset):
    prop = type(self)(self.fget, fset, self.fdel, self._name)
    return prop

def deleter(self, fdel):
    prop = type(self)(self.fget, self.fset, fdel, self._name)
    return prop

```

The `property()` builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through `Cell('b10').value`. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the value attribute in a property data descriptor:

```

class Cell:
    ...

    @property
    def value(self):
        "Recalculate the cell before returning value"
        self.recalc()
        return self._value

```

Either the built-in `property()` or our `Property()` equivalent would work in this example.

## Functions and methods

Python's object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Functions stored in class dictionaries get turned into methods when invoked. Methods only differ from regular functions in that the object instance is prepended to the other arguments. By convention, the instance is called *self* but could be called *this* or any other variable name.

Methods can be created manually with `types.MethodType` which is roughly equivalent to:

```
class MethodType:
    "Emulate PyMethod_Type in Objects/classobject.c"

    def __init__(self, func, obj):
        self.__func__ = func
        self.__self__ = obj

    def __call__(self, *args, **kwargs):
        func = self.__func__
        obj = self.__self__
        return func(obj, *args, **kwargs)
```

To support automatic creation of methods, functions include the `__get__()` method for binding methods during attribute access. This means that functions are non-data descriptors that return bound methods during dotted lookup from an instance. Here's how it works:

```
class Function:
    ...

    def __get__(self, obj, objtype=None):
```

```
"Simulate func_descr_get() in Objects/funcobject.c"
if obj is None:
    return self
return MethodType(self, obj)
```

Running the following class in the interpreter shows how the function descriptor works in practice:

```
class D:
    def f(self, x):
        return x
```

The function has a [qualified name](#) attribute to support introspection:

```
>>> D.f.__qualname__
'D.f'
```

Accessing the function through the class dictionary does not invoke `__get__()`. Instead, it just returns the underlying function object:

```
>>> D.__dict__['f']
<function D.f at 0x00C45070>
```

Dotted access from a class calls `__get__()` which just returns the underlying function unchanged:

```
>>> D.f
<function D.f at 0x00C45070>
```

The interesting behavior occurs during dotted access from an instance. The dotted lookup calls `__get__()` which returns a bound method object:

```
>>> d = D()
>>> d.f
<bound method D.f of <__main__.D object at 0x00B18C90>>
```

Internally, the bound method stores the underlying function and the bound instance:

```
>>> d.f.__func__
<function D.f at 0x00C45070>

>>> d.f.__self__
<__main__.D object at 0x1012e1f98>
```

If you have ever wondered where *self* comes from in regular methods or where *cls* comes from in class methods, this is it!

## Kinds of methods

Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a `__get__()` method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms an `obj.f(*args)` call into `f(obj, *args)`. Calling `cls.f(*args)` becomes `f(*args)`.

This chart summarizes the binding and its two most useful variants:

Called from an object	
<code>f(obj,*args)</code>	
Called from a class	
<code>f(*args)</code>	
<code>f(cls,*args)</code>	

## Static methods

Static methods return the underlying function without changes. Calling either `c.f` or `C.f` is the equivalent of a direct lookup into `object.__getattribute__(c, "f")` or `object.__getattribute__(C, "f")`. As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the `self` variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful

functions which are conceptually related but do not depend on the data. For instance, `erf(x)` is handy conversion routine that comes up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class:

```
s.erf(1.5) --> .9332 or Sample.erf(1.5) --> .9332.
```

Since static methods return the underlying function with no changes, the example calls are unexciting:

```
class E:
    @staticmethod
    def f(x):
        return x * 10
```

```
>>> E.f(3)
30
>>> E().f(3)
30
```

Using the non-data descriptor protocol, a pure Python version of `staticmethod()` would look like this:

```
import functools
```

```
class StaticMethod:
    "Emulate PyStaticMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f
        functools.update_wrapper(self, f)

    def __get__(self, obj, objtype=None):
        return self.f

    def __call__(self, *args, **kwargs):
        return self.f(*args, **kwargs)
```

The `functools.update_wrapper()` call adds a `__wrapped__` attribute that refers to the underlying function. Also it carries forward the attributes necessary to make the wrapper look like the

wrapped function: `__name__`, `__qualname__`, `__doc__`, and `__annotations__`.

## Class methods

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:

```
class F:
    @classmethod
    def f(cls, x):
        return cls.__name__, x

>>> F.f(3)
('F', 3)
>>> F().f(3)
('F', 3)
```

This behavior is useful whenever the method only needs to have a class reference and does not rely on data stored in a specific instance. One use for class methods is to create alternate class constructors. For example, the classmethod `dict.fromkeys()` creates a new dictionary from a list of keys. The pure Python equivalent is:

```
class Dict(dict):
    @classmethod
    def fromkeys(cls, iterable, value=None):
        "Emulate dict_fromkeys() in Objects/dictobject.c"
        d = cls()
        for key in iterable:
            d[key] = value
        return d
```

Now a new dictionary of unique keys can be constructed like this:

```
>>> d = Dict.fromkeys('abracadabra')
>>> type(d) is Dict
True
```

```
>>> d
{'a': None, 'b': None, 'r': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of `classmethod()` would look like this:

```
import functools

class ClassMethod:
    "Emulate PyClassMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f
        functools.update_wrapper(self, f)

    def __get__(self, obj, cls=None):
        if cls is None:
            cls = type(obj)
        if hasattr(type(self.f), '__get__'):
            # This code path was added in Python 3.9
            # and was deprecated in Python 3.11.
            return self.f.__get__(cls, cls)
        return MethodType(self.f, cls)
```

The code path for `hasattr(type(self.f), '__get__')` was added in Python 3.9 and makes it possible for `classmethod()` to support chained decorators. For example, a classmethod and property could be chained together. In Python 3.11, this functionality was deprecated.

```
class G:
    @classmethod
    @property
    def __doc__(cls):
        return f'A doc for {cls.__name__!r}'

>>> G.__doc__
"A doc for 'G'"
```

The `functools.update_wrapper()` call in `ClassMethod`

adds a `__wrapped__` attribute that refers to the underlying function. Also it carries forward the attributes necessary to make the wrapper look like the wrapped function: `__name__`, `__qualname__`, `__doc__`, and `__annotations__`.

## Member objects and `__slots__`

When a class defines `__slots__`, it replaces instance dictionaries with a fixed-length array of slot values. From a user point of view that has several effects:

1. Provides immediate detection of bugs due to misspelled attribute assignments. Only attribute names specified in `__slots__` are allowed:

```
class Vehicle:
    __slots__ = ('id_number', 'make', 'model')

>>> auto = Vehicle()
>>> auto.id_nubmer = 'VYE483814LQEX'
Traceback (most recent call last):
...
AttributeError: 'Vehicle' object has no attribute 'id_nu
```

2. Helps create immutable objects where descriptors manage access to private attributes stored in `__slots__`:

```
class Immutable:

    __slots__ = ('_dept', '_name')                # Replace the dict with slots

    def __init__(self, dept, name):
        self._dept = dept                        # Store to private attribute
        self._name = name                        # Store to private attribute

    @property                                    # Read-only
    def dept(self):
        return self._dept

    @property
```

```

def name(self):
    return self._name                                # Read-only

>>> mark = Immutable('Botany', 'Mark Watney')
>>> mark.dept
'Botany'
>>> mark.dept = 'Space Pirate'
Traceback (most recent call last):
...
AttributeError: property 'dept' of 'Immutable' object has no attribute 'dept'
>>> mark.location = 'Mars'
Traceback (most recent call last):
...
AttributeError: 'Immutable' object has no attribute 'location'

```

3. Saves memory. On a 64-bit Linux build, an instance with two attributes takes 48 bytes with `__slots__` and 152 bytes without.

This [flyweight design pattern](https://en.wikipedia.org/wiki/Flyweight_pattern) [https://en.wikipedia.org/wiki/Flyweight\_pattern] likely only matters when a large number of instances are going to be created.

4. Improves speed. Reading instance variables is 35% faster with `__slots__` (as measured with Python 3.10 on an Apple M1 processor).

5. Blocks tools like `functools.cached_property()` which require an instance dictionary to function correctly:

```

from functools import cached_property

class CP:
    __slots__ = ()                                # Eliminates instance dictionary

    @cached_property                              # Requires instance dictionary
    def pi(self):
        return 4 * sum((-1.0)**n / (2.0*n + 1.0)
                        for n in reversed(range(100_000)))

>>> CP().pi
Traceback (most recent call last):

```

...

TypeError: No '\_\_dict\_\_' attribute on 'CP' instance to o

It is not possible to create an exact drop-in pure Python version of `__slots__` because it requires direct access to C structures and control over object memory allocation. However, we can build a mostly faithful simulation where the actual C structure for slots is emulated by a private `_slotvalues` list. Reads and writes to that private structure are managed by member descriptors:

```
null = object()
```

```
class Member:
```

```
    def __init__(self, name, clsname, offset):
        'Emulate PyMemberDef in Include/structmember.h'
        # Also see descr_new() in Objects/descrobject.c
        self.name = name
        self.clsname = clsname
        self.offset = offset

    def __get__(self, obj, objtype=None):
        'Emulate member_get() in Objects/descrobject.c'
        # Also see PyMember_GetOne() in Python/structmem
        if obj is None:
            return self
        value = obj._slotvalues[self.offset]
        if value is null:
            raise AttributeError(self.name)
        return value

    def __set__(self, obj, value):
        'Emulate member_set() in Objects/descrobject.c'
        obj._slotvalues[self.offset] = value

    def __delete__(self, obj):
        'Emulate member_delete() in Objects/descrobject.c'
        value = obj._slotvalues[self.offset]
        if value is null:
```

```

        raise AttributeError(self.name)
    obj._slotvalues[self.offset] = null

```

```

def __repr__(self):
    'Emulate member_repr() in Objects/descrobject.c'
    return f'<Member {self.name!r} of {self.clsname!r}'

```

The **type.\_\_new\_\_()** method takes care of adding member objects to class variables:

```

class Type(type):
    'Simulate how the type metaclass adds member objects'

    def __new__(mcls, clsname, bases, mapping, **kwargs):
        'Emulate type_new() in Objects/typeobject.c'
        # type_new() calls PyTypeReady() which calls add_slot
        slot_names = mapping.get('slot_names', [])
        for offset, name in enumerate(slot_names):
            mapping[name] = Member(name, clsname, offset)
        return type.__new__(mcls, clsname, bases, mapping)

```

The **object.\_\_new\_\_()** method takes care of creating instances that have slots instead of an instance dictionary. Here is a rough simulation in pure Python:

```

class Object:
    'Simulate how object.__new__() allocates memory for'

    def __new__(cls, *args, **kwargs):
        'Emulate object_new() in Objects/typeobject.c'
        inst = super().__new__(cls)
        if hasattr(cls, 'slot_names'):
            empty_slots = [null] * len(cls.slot_names)
            object.__setattr__(inst, '_slotvalues', empty_slots)
        return inst

    def __setattr__(self, name, value):
        'Emulate _PyObject_GenericSetAttrWithDict() in Objects/object.c'
        cls = type(self)

```

```

        if hasattr(cls, 'slot_names') and name not in cls.slot_names:
            raise AttributeError(
                f'{cls.__name__!r} object has no attribute {name!r}'
            )
        super().__setattr__(name, value)

    def __delattr__(self, name):
        'Emulate _PyObject_GenericSetAttrWithDict() Object'
        cls = type(self)
        if hasattr(cls, 'slot_names') and name not in cls.slot_names:
            raise AttributeError(
                f'{cls.__name__!r} object has no attribute {name!r}'
            )
        super().__delattr__(name)

```

To use the simulation in a real class, just inherit from **Object** and set the **metaclass** to **Type**:

```

class H(Object, metaclass=Type):
    'Instance variables stored in slots'

    slot_names = ['x', 'y']

    def __init__(self, x, y):
        self.x = x
        self.y = y

```

At this point, the metaclass has loaded member objects for *x* and *y*:

```

>>> from pprint import pp
>>> pp(dict(vars(H)))
{'__module__': '__main__',
 '__doc__': 'Instance variables stored in slots',
 'slot_names': ['x', 'y'],
 '__init__': <function H.__init__ at 0x7fb5d302f9d0>,
 'x': <Member 'x' of 'H'>,
 'y': <Member 'y' of 'H'>}

```

When instances are created, they have a `slot_values` list where the attributes are stored:

```
>>> h = H(10, 20)
>>> vars(h)
{'_slotvalues': [10, 20]}
>>> h.x = 55
>>> vars(h)
{'_slotvalues': [55, 20]}
```

**Misspelled or unassigned attributes will raise an exception:**

```
>>> h.xz
Traceback (most recent call last):
...
AttributeError: 'H' object has no attribute 'xz'
```

# Enum HOWTO

An **Enum** is a set of symbolic names bound to unique values. They are similar to global variables, but they offer a more useful **repr()**, grouping, type-safety, and a few other features.

They are most useful when you have a variable that can take one of a limited selection of values. For example, the days of the week:

```
>>> from enum import Enum
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
...     SATURDAY = 6
...     SUNDAY = 7
```

Or perhaps the RGB primary colors:

```
>>> from enum import Enum
>>> class Color(Enum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
```

As you can see, creating an **Enum** is as simple as writing a class that inherits from **Enum** itself.

## Note

### Case of Enum Members

Because Enums are used to represent constants, and to help avoid issues with name clashes between mixin-class methods/

attributes and enum names, we strongly recommend using UPPER\_CASE names for members, and will be using that style in our examples.

Depending on the nature of the enum a member's value may or may not be important, but either way that value can be used to get the corresponding member:

```
>>> Weekday(3)
<Weekday.WEDNESDAY: 3>
```

As you can see, the `repr()` of a member shows the enum name, the member name, and the value. The `str()` of a member shows only the enum name and member name:

```
>>> print(Weekday.THURSDAY)
Weekday.THURSDAY
```

The *type* of an enumeration member is the enum it belongs to:

```
>>> type(Weekday.MONDAY)
<enum 'Weekday'>
>>> isinstance(Weekday.FRIDAY, Weekday)
True
```

Enum members have an attribute that contains just their **name**:

```
>>> print(Weekday.TUESDAY.name)
TUESDAY
```

Likewise, they have an attribute for their **value**:

```
>>> Weekday.WEDNESDAY.value
3
```

Unlike many languages that treat enumerations solely as name/value pairs, Python Enums can have behavior added. For example, `datetime.date` has two methods for returning the weekday: `weekday()` and `isoweekday()`. The difference is that one of them counts from 0-6 and the other from 1-7. Rather than keep track of that ourselves we can add a method to the **Weekday** enum

to extract the day from the **date** instance and return the matching enum member:

```
@classmethod
def from_date(cls, date):
    return cls(date.isoweekday())
```

The complete **Weekday** enum now looks like this:

```
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
...     SATURDAY = 6
...     SUNDAY = 7
...     #
...     @classmethod
...     def from_date(cls, date):
...         return cls(date.isoweekday())
```

Now we can find out what today is! Observe:

```
>>> from datetime import date
>>> Weekday.from_date(date.today())
<Weekday.TUESDAY: 2>
```

Of course, if you're reading this on some other day, you'll see that day instead.

This **Weekday** enum is great if our variable only needs one day, but what if we need several? Maybe we're writing a function to plot chores during a week, and don't want to use a **list** – we could use a different type of **Enum**:

```
>>> from enum import Flag
>>> class Weekday(Flag):
...     MONDAY = 1
...     TUESDAY = 2
```

```
...     WEDNESDAY = 4
...     THURSDAY = 8
...     FRIDAY = 16
...     SATURDAY = 32
...     SUNDAY = 64
```

We've changed two things: we're inherited from **Flag**, and the values are all powers of 2.

Just like the original **Weekday** enum above, we can have a single selection:

```
>>> first_week_day = Weekday.MONDAY
>>> first_week_day
<Weekday.MONDAY: 1>
```

But **Flag** also allows us to combine several members into a single variable:

```
>>> weekend = Weekday.SATURDAY | Weekday.SUNDAY
>>> weekend
<Weekday.SATURDAY|SUNDAY: 96>
```

You can even iterate over a **Flag** variable:

```
>>> for day in weekend:
...     print(day)
Weekday.SATURDAY
Weekday.SUNDAY
```

Okay, let's get some chores set up:

```
>>> chores_for_ethan = {
...     'feed the cat': Weekday.MONDAY | Weekday.WEDNESDAY,
...     'do the dishes': Weekday.TUESDAY | Weekday.THURSDAY,
...     'answer SO questions': Weekday.SATURDAY,
... }
```

And a function to display the chores for a given day:

```
>>> def show_chores(chores, day):
```

```

...     for chore, days in chores.items():
...         if day in days:
...             print(chore)
...
>>> show_chores(chores_for_ethan, Weekday.SATURDAY)
answer SO questions

```

In cases where the actual values of the members do not matter, you can save yourself some work and use `auto()` for the values:

```

>>> from enum import auto
>>> class Weekday(Flag):
...     MONDAY = auto()
...     TUESDAY = auto()
...     WEDNESDAY = auto()
...     THURSDAY = auto()
...     FRIDAY = auto()
...     SATURDAY = auto()
...     SUNDAY = auto()
...     WEEKEND = SATURDAY | SUNDAY

```

## Programmatic access to enumeration members and their attributes

Sometimes it's useful to access members in enumerations programmatically (i.e. situations where `Color.RED` won't do because the exact color is not known at program-writing time). Enum allows such access:

```

>>> Color(1)
<Color.RED: 1>
>>> Color(3)
<Color.BLUE: 3>

```

If you want to access enum members by *name*, use item access:

```

>>> Color['RED']
<Color.RED: 1>
>>> Color['GREEN']

```

```
<Color.GREEN: 2>
```

If you have an enum member and need its **name** or **value**:

```
>>> member = Color.RED
>>> member.name
'RED'
>>> member.value
1
```

## Duplicating enum members and values

Having two enum members with the same name is invalid:

```
>>> class Shape(Enum):
...     SQUARE = 2
...     SQUARE = 3
...
Traceback (most recent call last):
...
TypeError: 'SQUARE' already defined as 2
```

However, an enum member can have other names associated with it. Given two entries `A` and `B` with the same value (and `A` defined first), `B` is an alias for the member `A`. By-value lookup of the value of `A` will return the member `A`. By-name lookup of `A` will return the member `A`. By-name lookup of `B` will also return the member `A`:

```
>>> class Shape(Enum):
...     SQUARE = 2
...     DIAMOND = 1
...     CIRCLE = 3
...     ALIAS_FOR_SQUARE = 2
...
>>> Shape.SQUARE
<Shape.SQUARE: 2>
>>> Shape.ALIAS_FOR_SQUARE
<Shape.SQUARE: 2>
```

```
>>> Shape(2)
<Shape.SQUARE: 2>
```

### Note

Attempting to create a member with the same name as an already defined attribute (another member, a method, etc.) or attempting to create an attribute with the same name as a member is not allowed.

## Ensuring unique enumeration values

By default, enumerations allow multiple names as aliases for the same value. When this behavior isn't desired, you can use the `unique()` decorator:

```
>>> from enum import Enum, unique
>>> @unique
... class Mistake(Enum):
...     ONE = 1
...     TWO = 2
...     THREE = 3
...     FOUR = 3
...
Traceback (most recent call last):
...
ValueError: duplicate values found in <enum 'Mistake'>:
```

## Using automatic values

If the exact value is unimportant you can use `auto`:

```
>>> from enum import Enum, auto
>>> class Color(Enum):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
```

```
>>> [member.value for member in Color]
[1, 2, 3]
```

The values are chosen by `_generate_next_value_()`, which can be overridden:

```
>>> class AutoName(Enum):
...     @staticmethod
...     def _generate_next_value_(name, start, count, last_value):
...         return name
...
>>> class Ordinal(AutoName):
...     NORTH = auto()
...     SOUTH = auto()
...     EAST = auto()
...     WEST = auto()
...
>>> [member.value for member in Ordinal]
['NORTH', 'SOUTH', 'EAST', 'WEST']
```

### Note

The `_generate_next_value_()` method must be defined before any members.

## Iteration

Iterating over the members of an enum does not provide the aliases:

```
>>> list(Shape)
[<Shape.SQUARE: 2>, <Shape.DIAMOND: 1>, <Shape.CIRCLE: 3>]
>>> list(Weekday)
[<Weekday.MONDAY: 1>, <Weekday.TUESDAY: 2>, <Weekday.WEDNESDAY: 3>]
```

Note that the aliases `Shape.ALIAS_FOR_SQUARE` and `Weekday.WEEKEND` aren't shown.

The special attribute `__members__` is a read-only ordered mapping of names to members. It includes all names defined in the

enumeration, including the aliases:

```
>>> for name, member in Shape.__members__.items():
...     name, member
...
('SQUARE', <Shape.SQUARE: 2>)
('DIAMOND', <Shape.DIAMOND: 1>)
('CIRCLE', <Shape.CIRCLE: 3>)
('ALIAS_FOR_SQUARE', <Shape.SQUARE: 2>)
```

The `__members__` attribute can be used for detailed programmatic access to the enumeration members. For example, finding all the aliases:

```
>>> [name for name, member in Shape.__members__.items()
['ALIAS_FOR_SQUARE']]
```

### Note

Aliases for flags include values with multiple flags set, such as `3`, and no flags set, i.e. `0`.

## Comparisons

Enumeration members are compared by identity:

```
>>> Color.RED is Color.RED
True
>>> Color.RED is Color.BLUE
False
>>> Color.RED is not Color.BLUE
True
```

Ordered comparisons between enumeration values are *not* supported. Enum members are not integers (but see [IntEnum](#) below):

```
>>> Color.RED < Color.BLUE
Traceback (most recent call last):
```

```
File "<stdin>", line 1, in <module>
TypeError: '<' not supported between instances of 'Color'
```

Equality comparisons are defined though:

```
>>> Color.BLUE == Color.RED
False
>>> Color.BLUE != Color.RED
True
>>> Color.BLUE == Color.BLUE
True
```

Comparisons against non-enumeration values will always compare not equal (again, [IntEnum](#) was explicitly designed to behave differently, see below):

```
>>> Color.BLUE == 2
False
```

## Warning

It is possible to reload modules – if a reloaded module contains enums, they will be recreated, and the new members may not compare identical/equal to the original members.

## Allowed members and attributes of enumerations

Most of the examples above use integers for enumeration values. Using integers is short and handy (and provided by default by the [Functional API](#)), but not strictly enforced. In the vast majority of use-cases, one doesn't care what the actual value of an enumeration is. But if the value is important, enumerations can have arbitrary values.

Enumerations are Python classes, and can have methods and special methods as usual. If we have this enumeration:

```
>>> class Mood(Enum):
```

```

...     FUNKY = 1
...     HAPPY = 3
...
...     def describe(self):
...         # self is the member here
...         return self.name, self.value
...
...     def __str__(self):
...         return 'my custom str! {0}'.format(self.value)
...
...     @classmethod
...     def favorite_mood(cls):
...         # cls here is the enumeration
...         return cls.HAPPY
...

```

Then:

```

>>> Mood.favorite_mood()
<Mood.HAPPY: 3>
>>> Mood.HAPPY.describe()
('HAPPY', 3)
>>> str(Mood.FUNKY)
'my custom str! 1'

```

The rules for what is allowed are as follows: names that start and end with a single underscore are reserved by enum and cannot be used; all other attributes defined within an enumeration will become members of this enumeration, with the exception of special methods (`__str__()`, `__add__()`, etc.), descriptors (methods are also descriptors), and variable names listed in `__ignore__`.

Note: if your enumeration defines `__new__()` and/or `__init__()`, any value(s) given to the enum member will be passed into those methods. See [Planet](#) for an example.

## Note

The `__new__()` method, if defined, is used during creation of the Enum members; it is then replaced by Enum's `__new__()`

which is used after class creation for lookup of existing members. See [When to use `\_new\_\(\)` vs. `\_init\_\(\)`](#) for more details.

## Restricted Enum subclassing

A new [Enum](#) class must have one base enum class, up to one concrete data type, and as many [object](#)-based mixin classes as needed. The order of these base classes is:

```
class EnumName([mix-in, ...,] [data-type,] base-enum):  
    pass
```

Also, subclassing an enumeration is allowed only if the enumeration does not define any members. So this is forbidden:

```
>>> class MoreColor(Color):  
...     PINK = 17  
...  
Traceback (most recent call last):  
...  
TypeError: <enum 'MoreColor'> cannot extend <enum 'Color'
```

But this is allowed:

```
>>> class Foo(Enum):  
...     def some_behavior(self):  
...         pass  
...  
>>> class Bar(Foo):  
...     HAPPY = 1  
...     SAD = 2  
...
```

Allowing subclassing of enums that define members would lead to a violation of some important invariants of types and instances. On the other hand, it makes sense to allow sharing some common behavior between a group of enumerations. (See [OrderedEnum](#) for an example.)

# Dataclass support

When inheriting from a **dataclass**, the `__repr__()` omits the inherited class' name. For example:

```
>>> @dataclass
... class CreatureDataMixin:
...     size: str
...     legs: int
...     tail: bool = field(repr=False, default=True)
...
>>> class Creature(CreatureDataMixin, Enum):
...     BEETLE = 'small', 6
...     DOG = 'medium', 4
...
>>> Creature.DOG
<Creature.DOG: size='medium', legs=4>
```

Use the **dataclass()** argument `repr=False` to use the standard **repr()**.

*Changed in version 3.12:* Only the dataclass fields are shown in the value area, not the dataclass' name.

## Pickling

Enumerations can be pickled and unpickled:

```
>>> from test.test_enum import Fruit
>>> from pickle import dumps, loads
>>> Fruit.TOMATO is loads(dumps(Fruit.TOMATO))
True
```

The usual restrictions for pickling apply: picklable enums must be defined in the top level of a module, since unpickling requires them to be importable from that module.

### Note

With pickle protocol version 4 it is possible to easily pickle enums nested in other classes.

It is possible to modify how enum members are pickled/unpickled by defining `__reduce_ex__()` in the enumeration class. The default method is by-value, but enums with complicated values may want to use by-name:

```
>>> class MyEnum(Enum):  
...     __reduce_ex__ = enum.pickle_by_enum_name
```

### Note

Using by-name for flags is not recommended, as unnamed aliases will not unpickle.

## Functional API

The `Enum` class is callable, providing the following functional API:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG')  
>>> Animal  
<enum 'Animal'>  
>>> Animal.ANT  
<Animal.ANT: 1>  
>>> list(Animal)  
[<Animal.ANT: 1>, <Animal.BEE: 2>, <Animal.CAT: 3>, <Animal.DOG: 4>]
```

The semantics of this API resemble `namedtuple`. The first argument of the call to `Enum` is the name of the enumeration.

The second argument is the *source* of enumeration member names. It can be a whitespace-separated string of names, a sequence of names, a sequence of 2-tuples with key/value pairs, or a mapping (e.g. dictionary) of names to values. The last two options enable assigning arbitrary values to enumerations; the others auto-assign increasing integers starting with 1 (use the `start` parameter to specify a different starting value). A new class derived from `Enum` is returned. In other words, the above assignment to `Animal` is

equivalent to:

```
>>> class Animal(Enum):
...     ANT = 1
...     BEE = 2
...     CAT = 3
...     DOG = 4
...
```

The reason for defaulting to `1` as the starting number and not `0` is that `0` is `False` in a boolean sense, but by default enum members all evaluate to `True`.

Pickling enums created with the functional API can be tricky as frame stack implementation details are used to try and figure out which module the enumeration is being created in (e.g. it will fail if you use a utility function in a separate module, and also may not work on IronPython or Jython). The solution is to specify the module name explicitly as follows:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG', module=___
```

## Warning

If `module` is not supplied, and `Enum` cannot determine what it is, the new `Enum` members will not be unpicklable; to keep errors closer to the source, pickling will be disabled.

The new pickle protocol 4 also, in some circumstances, relies on `__qualname__` being set to the location where pickle will be able to find the class. For example, if the class was made available in class `SomeData` in the global scope:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG', qualname=___
```

The complete signature is:

```
Enum(
    value='NewEnumName',
    names=<...>,
```

```
*,
module='...',
qualname='...',
type=<mixed-in class>,
start=1,
)
```

## **value**

What the new enum class will record as its name.

## **names**

The enum members. This can be a whitespace- or comma-separated string (values will start at 1 unless otherwise specified):

```
'RED GREEN BLUE' | 'RED, GREEN, BLUE' | 'RED GREEN BLUE'
```

or an iterator of names:

```
['RED', 'GREEN', 'BLUE']
```

or an iterator of (name, value) pairs:

```
[('CYAN', 4), ('MAGENTA', 5), ('YELLOW', 6)]
```

or a mapping:

```
{ 'CHARTREUSE': 7, 'SEA_GREEN': 11, 'ROSEMARY': 12 }
```

## **module**

name of module where new enum class can be found.

## **qualname**

where in module new enum class can be found.

## **type**

type to mix in to new enum class.

## **start**

number to start counting at if only names are passed in.

*Changed in version 3.5:* The *start* parameter was added.

## Derived Enumerations

### IntEnum

The first variation of `Enum` that is provided is also a subclass of `int`. Members of an `IntEnum` can be compared to integers; by extension, integer enumerations of different types can also be compared to each other:

```
>>> from enum import IntEnum
>>> class Shape(IntEnum):
...     CIRCLE = 1
...     SQUARE = 2
...
>>> class Request(IntEnum):
...     POST = 1
...     GET = 2
...
>>> Shape == 1
False
>>> Shape.CIRCLE == 1
True
>>> Shape.CIRCLE == Request.POST
True
```

However, they still can't be compared to standard `Enum` enumerations:

```
>>> class Shape(IntEnum):
...     CIRCLE = 1
...     SQUARE = 2
...
>>> class Color(Enum):
...     RED = 1
```

```
...     GREEN = 2
...
>>> Shape.CIRCLE == Color.RED
False
```

**IntEnum** values behave like integers in other ways you'd expect:

```
>>> int(Shape.CIRCLE)
1
>>> ['a', 'b', 'c'][Shape.CIRCLE]
'b'
>>> [i for i in range(Shape.SQUARE)]
[0, 1]
```

## StrEnum

The second variation of **Enum** that is provided is also a subclass of **str**. Members of a **StrEnum** can be compared to strings; by extension, string enumerations of different types can also be compared to each other.

*New in version 3.11.*

## IntFlag

The next variation of **Enum** provided, **IntFlag**, is also based on **int**. The difference being **IntFlag** members can be combined using the bitwise operators (&, |, ^, ~) and the result is still an **IntFlag** member, if possible. Like **IntEnum**, **IntFlag** members are also integers and can be used wherever an **int** is used.

### Note

Any operation on an **IntFlag** member besides the bit-wise operations will lose the **IntFlag** membership.

Bit-wise operations that result in invalid **IntFlag** values will lose the **IntFlag** membership. See **FlagBoundary** for details.

*New in version 3.6.*

*Changed in version 3.11.*

Sample **IntFlag** class:

```
>>> from enum import IntFlag
>>> class Perm(IntFlag):
...     R = 4
...     W = 2
...     X = 1
...
>>> Perm.R | Perm.W
<Perm.R|W: 6>
>>> Perm.R + Perm.W
6
>>> RW = Perm.R | Perm.W
>>> Perm.R in RW
True
```

It is also possible to name the combinations:

```
>>> class Perm(IntFlag):
...     R = 4
...     W = 2
...     X = 1
...     RWX = 7
...
>>> Perm.RWX
<Perm.RWX: 7>
>>> ~Perm.RWX
<Perm: 0>
>>> Perm(7)
<Perm.RWX: 7>
```

## Note

Named combinations are considered aliases. Aliases do not show up during iteration, but can be returned from by-value lookups.

*Changed in version 3.11.*

Another important difference between **IntFlag** and **Enum** is that if no flags are set (the value is 0), its boolean evaluation is **False**:

```
>>> Perm.R & Perm.X
<Perm: 0>
>>> bool(Perm.R & Perm.X)
False
```

Because **IntFlag** members are also subclasses of **int** they can be combined with them (but may lose **IntFlag** membership:

```
>>> Perm.X | 4
<Perm.R|X: 5>

>>> Perm.X | 8
9
```

## Note

The negation operator, `~`, always returns an **IntFlag** member with a positive value:

```
>>> (~Perm.X).value == (Perm.R|Perm.W).value == 6
True
```

**IntFlag** members can also be iterated over:

```
>>> list(RW)
[<Perm.R: 4>, <Perm.W: 2>]
```

*New in version 3.11.*

## Flag

The last variation is **Flag**. Like **IntFlag**, **Flag** members can be combined using the bitwise operators (`&`, `|`, `^`, `~`). Unlike **IntFlag**, they cannot be combined with, nor compared against, any other **Flag** enumeration, nor **int**. While it is possible to specify the

values directly it is recommended to use `auto` as the value and let `Flag` select an appropriate value.

*New in version 3.6.*

Like `IntFlag`, if a combination of `Flag` members results in no flags being set, the boolean evaluation is `False`:

```
>>> from enum import Flag, auto
>>> class Color(Flag):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.RED & Color.GREEN
<Color: 0>
>>> bool(Color.RED & Color.GREEN)
False
```

Individual flags should have values that are powers of two (1, 2, 4, 8, ...), while combinations of flags will not:

```
>>> class Color(Flag):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...     WHITE = RED | BLUE | GREEN
...
>>> Color.WHITE
<Color.WHITE: 7>
```

Giving a name to the “no flags set” condition does not change its boolean value:

```
>>> class Color(Flag):
...     BLACK = 0
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
```

```
>>> Color.BLACK
<Color.BLACK: 0>
>>> bool(Color.BLACK)
False
```

**Flag** members can also be iterated over:

```
>>> purple = Color.RED | Color.BLUE
>>> list(purple)
[<Color.RED: 1>, <Color.BLUE: 2>]
```

*New in version 3.11.*

## Note

For the majority of new code, **Enum** and **Flag** are strongly recommended, since **IntEnum** and **IntFlag** break some semantic promises of an enumeration (by being comparable to integers, and thus by transitivity to other unrelated enumerations). **IntEnum** and **IntFlag** should be used only in cases where **Enum** and **Flag** will not do; for example, when integer constants are replaced with enumerations, or for interoperability with other systems.

## Others

While **IntEnum** is part of the **enum** module, it would be very simple to implement independently:

```
class IntEnum(int, Enum):
    pass
```

This demonstrates how similar derived enumerations can be defined; for example a **FloatEnum** that mixes in **float** instead of **int**.

Some rules:

1. When subclassing **Enum**, mix-in types must appear before **Enum** itself in the sequence of bases, as in the **IntEnum**

example above.

2. Mix-in types must be subclassable. For example, `bool` and `range` are not subclassable and will throw an error during Enum creation if used as the mix-in type.
3. While `Enum` can have members of any type, once you mix in an additional type, all the members must have values of that type, e.g. `int` above. This restriction does not apply to mix-ins which only add methods and don't specify another type.
4. When another data type is mixed in, the `value` attribute is *not the same* as the enum member itself, although it is equivalent and will compare equal.
5. A data type is a mixin that defines `__new__()`, or a `dataclass`
6. %-style formatting: `%s` and `%r` call the `Enum` class's `__str__()` and `__repr__()` respectively; other codes (such as `%i` or `%h` for `IntEnum`) treat the enum member as its mixed-in type.
7. Formatted string literals, `str.format()`, and `format()` will use the enum's `__str__()` method.

## Note

Because `IntEnum`, `IntFlag`, and `StrEnum` are designed to be drop-in replacements for existing constants, their `__str__()` method has been reset to their data types' `__str__()` method.

## When to use `__new__()` vs. `__init__()`

`__new__()` must be used whenever you want to customize the actual value of the `Enum` member. Any other modifications may go in either `__new__()` or `__init__()`, with `__init__()` being preferred.

For example, if you want to pass several items to the constructor, but only want one of them to be the value:

```
>>> class Coordinate(bytes, Enum):
...     """
...     Coordinate with binary codes that can be indexed
```

```

...     """
...     def __new__(cls, value, label, unit):
...         obj = bytes.__new__(cls, [value])
...         obj._value_ = value
...         obj.label = label
...         obj.unit = unit
...         return obj
...     PX = (0, 'P.X', 'km')
...     PY = (1, 'P.Y', 'km')
...     VX = (2, 'V.X', 'km/s')
...     VY = (3, 'V.Y', 'km/s')
...

```

```

>>> print(Coordinate['PY'])
Coordinate.PY

```

```

>>> print(Coordinate(3))
Coordinate.VY

```

## Warning

*Do not* call `super().__new__()`, as the lookup-only `__new__` is the one that is found; instead, use the data type directly.

## Finer Points

### Supported `__dunder__` names

`__members__` is a read-only ordered mapping of `member_name:member` items. It is only available on the class.

`__new__()`, if specified, must create and return the enum members; it is also a very good idea to set the member's `__value__` appropriately. Once all the members are created it is no longer used.

### Supported `__sunder__` names

- `_name_` – name of the member
- `_value_` – value of the member; can be set / modified in `__new__`
- `_missing_` – a lookup function used when a value is not found; may be overridden
- `_ignore_` – a list of names, either as a `list` or a `str`, that will not be transformed into members, and will be removed from the final class
- `_order_` – used in Python 2/3 code to ensure member order is consistent (class attribute, removed during class creation)
- `_generate_next_value_` – used by the `Functional API` and by `auto` to get an appropriate value for an enum member; may be overridden

## Note

For standard `Enum` classes the next value chosen is the last value seen incremented by one.

For `Flag` classes the next value chosen will be the next highest power-of-two, regardless of the last value seen.

*New in version 3.6:* `_missing_`, `_order_`,  
`_generate_next_value_`

*New in version 3.7:* `_ignore_`

To help keep Python 2 / Python 3 code in sync an `_order_` attribute can be provided. It will be checked against the actual order of the enumeration and raise an error if the two do not match:

```
>>> class Color(Enum):
...     _order_ = 'RED GREEN BLUE'
...     RED = 1
...     BLUE = 3
...     GREEN = 2
...
Traceback (most recent call last):
...
```

```
TypeError: member order does not match _order_:
  ['RED', 'BLUE', 'GREEN']
  ['RED', 'GREEN', 'BLUE']
```

## Note

In Python 2 code the `_order_` attribute is necessary as definition order is lost before it can be recorded.

## Private names

**Private names** are not converted to enum members, but remain normal attributes.

*Changed in version 3.11.*

## Enum member type

Enum members are instances of their enum class, and are normally accessed as `EnumClass.member`. In certain situations, such as writing custom enum behavior, being able to access one member directly from another is useful, and is supported; however, in order to avoid name clashes between member names and attributes/methods from mixed-in classes, upper-case names are strongly recommended.

*Changed in version 3.5.*

## Creating members that are mixed with other data types

When subclassing other data types, such as `int` or `str`, with an **Enum**, all values after the `=` are passed to that data type's constructor. For example:

```
>>> class MyEnum(IntEnum):           # help(int) -> int(x, ba
...     example = '11', 16           # so x='11' and base=16
...
>>> MyEnum.example.value            # and hex(11) is...
17
```

## Boolean value of Enum classes and members

Enum classes that are mixed with non-Enum types (such as `int`, `str`, etc.) are evaluated according to the mixed-in type's rules; otherwise, all members evaluate as `True`. To make your own enum's boolean evaluation depend on the member's value add the following to your class:

```
def __bool__(self):
    return bool(self.value)
```

Plain Enum classes always evaluate as `True`.

## Enum classes with methods

If you give your enum subclass extra methods, like the `Planet` class below, those methods will show up in a `dir()` of the member, but not of the class:

```
>>> dir(Planet)
['EARTH', 'JUPITER', 'MARS', 'MERCURY', 'NEPTUNE', 'SATURN']
>>> dir(Planet.EARTH)
['__class__', '__doc__', '__module__', 'mass', 'name', 'radius']
```

## Combining members of Flag

Iterating over a combination of `Flag` members will only return the members that are comprised of a single bit:

```
>>> class Color(Flag):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
...     MAGENTA = RED | BLUE
...     YELLOW = RED | GREEN
...     CYAN = GREEN | BLUE
...
>>> Color(3) # named combination
<Color.YELLOW: 3>
```

```
>>> Color(7)          # not named combination
<Color.RED|GREEN|BLUE: 7>
```

## Flag and IntFlag minutia

Using the following snippet for our examples:

```
>>> class Color(IntFlag):
...     BLACK = 0
...     RED = 1
...     GREEN = 2
...     BLUE = 4
...     PURPLE = RED | BLUE
...     WHITE = RED | GREEN | BLUE
...
```

the following are true:

- single-bit flags are canonical
- multi-bit and zero-bit flags are aliases
- only canonical flags are returned during iteration:

```
>>> list(Color.WHITE)
[<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE: 4>]
```

- negating a flag or flag set returns a new flag/flag set with the corresponding positive integer value:

```
>>> Color.BLUE
<Color.BLUE: 4>
```

```
>>> ~Color.BLUE
<Color.RED|GREEN: 3>
```

- names of pseudo-flags are constructed from their members' names:

```
>>> (Color.RED | Color.GREEN).name
'RED|GREEN'
```

- multi-bit flags, aka aliases, can be returned from operations:

```
>>> Color.RED | Color.BLUE
<Color.PURPLE: 5>
```

```
>>> Color(7) # or Color(-1)
<Color.WHITE: 7>
```

```
>>> Color(0)
<Color.BLACK: 0>
```

- membership / containment checking: zero-valued flags are always considered to be contained:

```
>>> Color.BLACK in Color.WHITE
True
```

otherwise, only if all bits of one flag are in the other flag will True be returned:

```
>>> Color.PURPLE in Color.WHITE
True
```

```
>>> Color.GREEN in Color.PURPLE
False
```

There is a new boundary mechanism that controls how out-of-range / invalid bits are handled: `STRICT`, `CONFORM`, `EJECT`, and `KEEP`:

- `STRICT` -> raises an exception when presented with invalid values
- `CONFORM` -> discards any invalid bits
- `EJECT` -> lose Flag status and become a normal int with the given value
- `KEEP` -> keep the extra bits
  - keeps Flag status and extra bits
  - extra bits do not show up in iteration
  - extra bits do show up in `repr()` and `str()`

The default for Flag is `STRICT`, the default for `IntFlag` is `EJECT`, and the default for `_convert_` is `KEEP` (see

`ssl.Options` for an example of when `KEEP` is needed).

## How are Enums and Flags different?

Enums have a custom metaclass that affects many aspects of both derived `Enum` classes and their instances (members).

### Enum Classes

The `EnumType` metaclass is responsible for providing the `__contains__()`, `__dir__()`, `__iter__()` and other methods that allow one to do things with an `Enum` class that fail on a typical class, such as `list(Color)` or `some_enum_var in Color`. `EnumType` is responsible for ensuring that various other methods on the final `Enum` class are correct (such as `__new__()`, `__getnewargs__()`, `__str__()` and `__repr__()`).

### Flag Classes

Flags have an expanded view of aliasing: to be canonical, the value of a flag needs to be a power-of-two value, and not a duplicate name. So, in addition to the `Enum` definition of alias, a flag with no value (a.k.a. `0`) or with more than one power-of-two value (e.g. `3`) is considered an alias.

### Enum Members (aka instances)

The most interesting thing about enum members is that they are singletons. `EnumType` creates them all while it is creating the enum class itself, and then puts a custom `__new__()` in place to ensure that no new ones are ever instantiated by returning only the existing member instances.

### Flag Members

Flag members can be iterated over just like the `Flag` class, and only the canonical members will be returned. For example:

```
>>> list(Color)
```

```
[<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE: 4>]
```

(Note that BLACK, PURPLE, and WHITE do not show up.)

Inverting a flag member returns the corresponding positive value, rather than a negative value — for example:

```
>>> ~Color.RED
<Color.GREEN|BLUE: 6>
```

Flag members have a length corresponding to the number of power-of-two values they contain. For example:

```
>>> len(Color.PURPLE)
2
```

## Enum Cookbook

While `Enum`, `IntEnum`, `StrEnum`, `Flag`, and `IntFlag` are expected to cover the majority of use-cases, they cannot cover them all. Here are recipes for some different types of enumerations that can be used directly, or as examples for creating one's own.

### Omitting values

In many use-cases, one doesn't care what the actual value of an enumeration is. There are several ways to define this type of simple enumeration:

- use instances of `auto` for the value
- use instances of `object` as the value
- use a descriptive string as the value
- use a tuple as the value and a custom `__new__()` to replace the tuple with an `int` value

Using any of these methods signifies to the user that these values are not important, and also enables one to add, remove, or reorder members without having to renumber the remaining members.

Using `auto`

Using **auto** would look like:

```
>>> class Color(Enum):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.GREEN
<Color.GREEN: 3>
```

## Using **object**

Using **object** would look like:

```
>>> class Color(Enum):
...     RED = object()
...     GREEN = object()
...     BLUE = object()
...
>>> Color.GREEN
<Color.GREEN: <object object at 0x...>>
```

This is also a good example of why you might want to write your own **\_\_repr\_\_()**:

```
>>> class Color(Enum):
...     RED = object()
...     GREEN = object()
...     BLUE = object()
...     def __repr__(self):
...         return "<%s.%s>" % (self.__class__.__name__,
...
...
>>> Color.GREEN
<Color.GREEN>
```

## Using a descriptive string

Using a string as the value would look like:

`__init__` to handle any extra arguments:

```
>>> class Swatch(AutoNumber):
...     def __init__(self, pantone='unknown'):
...         self.pantone = pantone
...         AUBURN = '3497'
...         SEA_GREEN = '1246'
...         BLEACHED_CORAL = () # New color, no Pantone code
...
>>> Swatch.SEA_GREEN
<Swatch.SEA_GREEN: 2>
>>> Swatch.SEA_GREEN.pantone
'1246'
>>> Swatch.BLEACHED_CORAL.pantone
'unknown'
```

## Note

The `__new__()` method, if defined, is used during creation of the Enum members; it is then replaced by Enum's `__new__()` which is used after class creation for lookup of existing members.

## Warning

*Do not* call `super().__new__()`, as the lookup-only `__new__` is the one that is found; instead, use the data type directly – e.g.:

```
obj = int.__new__(cls, value)
```

## OrderedEnum

An ordered enumeration that is not based on `IntEnum` and so maintains the normal `Enum` invariants (such as not being comparable to other enumerations):

```
>>> class OrderedEnum(Enum):
...     def __ge__(self, other):
...         if self.__class__ is other.__class__:
```

```

...         return self.value >= other.value
...     return NotImplemented
...     def __gt__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value > other.value
...         return NotImplemented
...     def __le__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value <= other.value
...         return NotImplemented
...     def __lt__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value < other.value
...         return NotImplemented
...
>>> class Grade(OrderedEnum):
...     A = 5
...     B = 4
...     C = 3
...     D = 2
...     F = 1
...
>>> Grade.C < Grade.A
True

```

## DuplicateFreeEnum

Raises an error if a duplicate member value is found instead of creating an alias:

```

>>> class DuplicateFreeEnum(Enum):
...     def __init__(self, *args):
...         cls = self.__class__
...         if any(self.value == e.value for e in cls):
...             a = self.name
...             e = cls(self.value).name
...             raise ValueError(
...                 "aliases not allowed in DuplicateFreeEnum:
...                 % (a, e))

```

```

...
>>> class Color(DuplicateFreeEnum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
...     GRENE = 2
...
Traceback (most recent call last):
...
ValueError: aliases not allowed in DuplicateFreeEnum: '

```

## Note

This is a useful example for subclassing Enum to add or change other behaviors as well as disallowing aliases. If the only desired change is disallowing aliases, the `unique()` decorator can be used instead.

## Planet

If `__new__()` or `__init__()` is defined, the value of the enum member will be passed to those methods:

```

>>> class Planet(Enum):
...     MERCURY = (3.303e+23, 2.4397e6)
...     VENUS   = (4.869e+24, 6.0518e6)
...     EARTH   = (5.976e+24, 6.37814e6)
...     MARS    = (6.421e+23, 3.3972e6)
...     JUPITER = (1.9e+27, 7.1492e7)
...     SATURN  = (5.688e+26, 6.0268e7)
...     URANUS  = (8.686e+25, 2.5559e7)
...     NEPTUNE = (1.024e+26, 2.4746e7)
...     def __init__(self, mass, radius):
...         self.mass = mass          # in kilograms
...         self.radius = radius      # in meters
...     @property
...     def surface_gravity(self):
...         # universal gravitational constant (m3 kg-1

```

```

...         G = 6.67300E-11
...         return G * self.mass / (self.radius * self.r
...
>>> Planet.EARTH.value
(5.976e+24, 6378140.0)
>>> Planet.EARTH.surface_gravity
9.802652743337129

```

## TimePeriod

An example to show the `_ignore_` attribute in use:

```

>>> from datetime import timedelta
>>> class Period(timedelta, Enum):
...     "different lengths of time"
...     _ignore_ = 'Period i'
...     Period = vars()
...     for i in range(367):
...         Period['day_%d' % i] = i
...
>>> list(Period)[:2]
[<Period.day_0: datetime.timedelta(0)>, <Period.day_1: c
>>> list(Period)[-2:]
[<Period.day_365: datetime.timedelta(days=365)>, <Period

```

## Subclassing EnumType

While most enum needs can be met by customizing [Enum](#) subclasses, either with class decorators or custom functions, [EnumType](#) can be subclassed to provide a different Enum experience.

# Functional Programming HOWTO

Author

A. M. Kuchling

Release

0.32

In this document, we'll take a tour of Python's features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as [iterators](#) and [generators](#) and relevant library modules such as [itertools](#) and [functools](#).

## Introduction

This section explains the basic concept of functional programming; if you're just interested in learning about Python language features, skip to the next section on [Iterators](#).

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program's input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you're most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.

- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don't force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don't have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize one particular approach to programming. This often makes it difficult to write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren't visible in the function's return value. Functions that have no side effects at all are called **purely functional**. Avoiding side effects means not using data structures that get updated as a program runs; every function's output must only depend on its input.

Some languages are very strict about purity and don't even have assignment statements such as `a=3` or `c = a + b`, but it's difficult to avoid all side effects, such as printing to the screen or writing to a disk file. Another example is a call to the `print()` or `time.sleep()` function, neither of which returns a useful value. Both are called only for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won't go to the extreme of avoiding all I/O or all assignments; instead, they'll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won't modify global variables or have other side effects.

Functional programming can be considered the opposite of object-oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

## Formal provability

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program's source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down **invariants**, properties of the input data and of the program's

variables that are always true. For each line of code, you then show that if invariants X and Y are true **before** the line is executed, the slightly different invariants X' and Y' are true **after** the line is executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program's output.

Functional programming's avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there's an error in it, and you wrongly believe you've proved the program correct.

## Modularity

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It's easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

## Ease of debugging and testing

Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn't work, each function is an interface point where you can check that the data are correct. You can look at the intermediate inputs and outputs to quickly isolate the function that's responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don't depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

## Composability

As you work on a functional-style program, you'll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you'll form a personal library of utilities. Often you'll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.

## Iterators

I'll start by looking at a Python language feature that's an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called `__next__()` that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, `__next__()` must raise the `StopIteration` exception. Iterators don't have to be finite, though; it's perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in `iter()` function takes an arbitrary object and tries to return an iterator that will return the object's contents or elements, raising `TypeError` if the object doesn't support iteration. Several of Python's built-in data types support iteration, the most common being lists and dictionaries. An object is called `iterable` if you can

get an iterator for it.

You can experiment with the iteration interface manually:

```
>>> L = [1, 2, 3]
>>> it = iter(L)
>>> it
<...iterator object at ...>
>>> it.__next__() # same as next(it)
1
>>> next(it)
2
>>> next(it)
3
>>> next(it)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
StopIteration
>>>
```

Python expects iterable objects in several different contexts, the most important being the **for** statement. In the statement **for X in Y**, Y must be an iterator or some object for which **iter()** can create an iterator. These two statements are equivalent:

```
for i in iter(obj):
    print(i)
```

```
for i in obj:
    print(i)
```

Iterators can be materialized as lists or tuples by using the **list()** or **tuple()** constructor functions:

```
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return N elements, you can unpack them into an N-tuple:

```
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> a, b, c = iterator
>>> a, b, c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator argument and will return the largest or smallest element. The "in" and "not in" operators also support iterators: `X in iterator` is true if X is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; `max()`, `min()` will never return, and if the element X never appears in the stream, the "in" and "not in" operators won't return either.

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the `__next__()` method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

## Data Types That Support Iterators

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling `iter()` on a dictionary returns an iterator that will loop over the dictionary's keys:

```
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May':
...      'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov':
>>> for key in m:
...     print(key, m[key])
Jan 1
```

Feb 2  
Mar 3  
Apr 4  
May 5  
Jun 6  
Jul 7  
Aug 8  
Sep 9  
Oct 10  
Nov 11  
Dec 12

Note that starting with Python 3.7, dictionary iteration order is guaranteed to be the same as the insertion order. In earlier versions, the behaviour was unspecified and could vary between implementations.

Applying `iter()` to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over values or key/value pairs, you can explicitly call the `values()` or `items()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of (key, value) tuples:

```
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US',  
>>> dict(iter(L))  
{'Italy': 'Rome', 'France': 'Paris', 'US': 'Washington D
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```
for line in file:  
    # do something for each line  
    ...
```

Sets can take their contents from an iterable and let you iterate over the set's elements:

```
>>> S = {2, 3, 5, 7, 11, 13}
```

```
>>> for i in S:
...     print(i)
2
3
5
7
11
13
```

## Generator expressions and list comprehensions

Two common operations on an iterator's output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: “listcomps” and “genexps”) are a concise notation for such operations, borrowed from the functional programming language Haskell (<https://www.haskell.org/>). You can strip all the whitespace from a stream of strings with the following code:

```
>>> line_list = [' line 1\n', 'line 2  \n', ' \n', '']

>>> # Generator expression -- returns iterator
>>> stripped_iter = (line.strip() for line in line_list)

>>> # List comprehension -- returns list
>>> stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an “if” condition:

```
>>> stripped_list = [line.strip() for line in line_list
...                  if line != ""]
```

With a list comprehension, you get back a Python list; `stripped_list` is a list containing the resulting lines, not an

iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This means that list comprehensions aren't useful if you're working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.

Generator expressions are surrounded by parentheses (“()”) and list comprehensions are surrounded by square brackets (“[]”). Generator expressions have the form:

```
( expression for expr in sequence1
    if condition1
    for expr2 in sequence2
    if condition2
    for expr3 in sequence3
    ...
    if condition3
    for exprN in sequenceN
    if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of `expression`. The `if` clauses are all optional; if present, `expression` is only evaluated and added to the result when `condition` is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects())
```

The `for...in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are iterated over from left to right, **not** in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements

from sequence1 and sequence2.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:

```
for expr1 in sequence1:
    if not (condition1):
        continue    # Skip this element
for expr2 in sequence2:
    if not (condition2):
        continue    # Skip this element
...
for exprN in sequenceN:
    if not (conditionN):
        continue    # Skip this element

    # Output the value of
    # the expression.
```

This means that when there are multiple `for...in` clauses but no `if` clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```
>>> seq1 = 'abc'
>>> seq2 = (1, 2, 3)
>>> [(x, y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3),
 ('b', 1), ('b', 2), ('b', 3),
 ('c', 1), ('c', 2), ('c', 3)]
```

To avoid introducing an ambiguity into Python's grammar, if expression is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```
# Syntax error
[x, y for x in seq1 for y in seq2]
# Correct
[(x, y) for x in seq1 for y in seq2]
```

# Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You're doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren't thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here's the simplest example of a generator function:

```
>>> def generate_ints(N):  
...     for i in range(N):  
...         yield i
```

Any function containing a `yield` keyword is a generator function; this is detected by Python's `bytecode` compiler which compiles the function specially as a result.

When you call a generator function, it doesn't return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator's state of execution is suspended and local variables are preserved. On the next call to the generator's `__next__()` method, the function will resume executing.

Here's a sample usage of the `generate_ints()` generator:

```
>>> gen = generate_ints(3)  
>>> gen
```

```

<generator object generate_ints at ...>
>>> next(gen)
0
>>> next(gen)
1
>>> next(gen)
2
>>> next(gen)
Traceback (most recent call last):
  File "stdin", line 1, in <module>
  File "stdin", line 2, in generate_ints
StopIteration

```

You could equally write `for i in generate_ints(5), or a, b, c = generate_ints(3).`

Inside a generator function, `return value` causes `StopIteration(value)` to be raised from the `__next__()` method. Once this happens, or the bottom of the function is reached, the procession of values ends and the generator cannot yield any further values.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `__next__()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class can be much messier.

The test suite included with Python's library, [Lib/test/test\\_generators.py](https://github.com/python/cpython/tree/3.12/Lib/test/test_generators.py) [[https://github.com/python/cpython/tree/3.12/Lib/test/test\\_generators.py](https://github.com/python/cpython/tree/3.12/Lib/test/test_generators.py)], contains a number of more interesting examples. Here's one generator that implements an in-order traversal of a tree using generators recursively.

```

# A recursive generator that generates Tree leaves in in
def inorder(t):
    if t:
        for x in inorder(t.left):

```

```
        yield x

    yield t.label

    for x in inorder(t.right):
        yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight's Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

## Passing values into a generator

In Python 2.4 and earlier, generators only produced output. Once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.

In Python 2.5 there's a simple way to pass values into a generator. `yield` became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

([PEP 342](https://peps.python.org/pep-0342/) [https://peps.python.org/pep-0342/] explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val`

```
= (yield i) + 12.)
```

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular `__next__()` method is called, the `yield` returns `None`.

Here's a simple counter that increments by 1 and allows changing the value of the internal counter.

```
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here's an example of changing the counter:

```
>>> it = counter(10)
>>> next(it)
0
>>> next(it)
1
>>> it.send(8)
8
>>> next(it)
9
>>> next(it)
Traceback (most recent call last):
  File "t.py", line 15, in <module>
    it.next()
StopIteration
```

Because `yield` will often be returning `None`, you should always check for this case. Don't just use its value in expressions unless you're sure that the `send()` method will be the only method used

to resume your generator function.

In addition to `send()`, there are two other methods on generators:

- `throw(value)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator's execution is paused.
- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator's code must either raise `GeneratorExit` or `StopIteration`; catching the exception and doing anything else is illegal and will trigger a `RuntimeError`. `close()` will also be called by Python's garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally: suite` instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become **coroutines**, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements).

## Built-in functions

Let's look in more detail at built-in functions often used with iterators.

Two of Python's built-in functions, `map()` and `filter()` duplicate the features of generator expressions:

`map(f, iterA, iterB, ...)` returns an iterator over the sequence

```

f(iterA[0], iterB[0]), f(iterA[1], iterB[1]),
f(iterA[2], iterB[2]), ....

>>> def upper(s):
...     return s.upper()

>>> list(map(upper, ['sentence', 'fragment']))
['SENTENCE', 'FRAGMENT']
>>> [upper(s) for s in ['sentence', 'fragment']]
['SENTENCE', 'FRAGMENT']

```

You can of course achieve the same effect with a list comprehension.

**filter(predicate, iter)** returns an iterator over all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A **predicate** is a function that returns the truth value of some condition; for use with **filter()**, the predicate must take a single value.

```

>>> def is_even(x):
...     return (x % 2) == 0

>>> list(filter(is_even, range(10)))
[0, 2, 4, 6, 8]

```

This can also be written as a list comprehension:

```

>>> list(x for x in range(10) if is_even(x))
[0, 2, 4, 6, 8]

```

**enumerate(iter, start=0)** counts off the elements in the iterable returning 2-tuples containing the count (from *start*) and each element.

```

>>> for item in enumerate(['subject', 'verb', 'object']):
...     print(item)
(0, 'subject')
(1, 'verb')
(2, 'object')

```

**enumerate()** is often used when looping through a list and recording the indexes at which certain conditions are met:

```
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print('Blank line at line #%i' % i)
```

**sorted(iterable, key=None, reverse=False)** collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The *key* and *reverse* arguments are passed through to the constructed list's **sort()** method.

```
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[769, 2207, 6213, 6431, 7953, 8442, 9828, 9878]
>>> sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]
```

(For a more detailed discussion of sorting, see the [Sorting HOW TO](#).)

The **any(iter)** and **all(iter)** built-ins look at the truth values of an iterable's contents. **any()** returns `True` if any element in the iterable is a true value, and **all()** returns `True` if all of the elements are true values:

```
>>> any([0, 1, 0])
True
>>> any([0, 0, 0])
False
>>> any([1, 1, 1])
True
>>> all([0, 1, 0])
False
>>> all([0, 0, 0])
```

```
False
>>> all([1, 1, 1])
True
```

`zip(iterA, iterB, ...)` takes one element from each iterable and returns them in a tuple:

```
zip(['a', 'b', 'c'], (1, 2, 3)) =>
    ('a', 1), ('b', 2), ('c', 3)
```

It doesn't construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they're requested. (The technical term for this behaviour is [lazy evaluation](https://en.wikipedia.org/wiki/Lazy_evaluation) [https://en.wikipedia.org/wiki/Lazy\_evaluation].)

This iterator is intended to be used with iterables that are all of the same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

```
zip(['a', 'b'], (1, 2, 3)) =>
    ('a', 1), ('b', 2)
```

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can't go on to use the iterators further because you risk skipping a discarded element.

## The `itertools` module

The `itertools` module contains a number of commonly used iterators as well as functions for combining several iterators. This section will introduce the module's contents by showing small examples.

The module's functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator's elements as function

arguments.

- Functions for selecting portions of an iterator's output.
- A function for grouping an iterator's output.

## Creating new iterators

**`itertools.count(start, step)`** returns an infinite stream of evenly spaced values. You can optionally supply the starting number, which defaults to 0, and the interval between numbers, which defaults to 1:

```
itertools.count() =>
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
itertools.count(10) =>
    10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
itertools.count(10, 5) =>
    10, 15, 20, 25, 30, 35, 40, 45, 50, 55, ...
```

**`itertools.cycle(iter)`** saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.

```
itertools.cycle([1, 2, 3, 4, 5]) =>
    1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```

**`itertools.repeat(elem, [n])`** returns the provided element *n* times, or returns the element endlessly if *n* is not provided.

```
itertools.repeat('abc') =>
    abc, abc, abc, abc, abc, abc, abc, abc, abc, abc, ...
itertools.repeat('abc', 5) =>
    abc, abc, abc, abc, abc
```

**`itertools.chain(iterA, iterB, ...)`** takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

```
itertools.chain(['a', 'b', 'c'], (1, 2, 3)) =>
```

```
a, b, c, 1, 2, 3
```

**`itertools.islice(iter, [start], stop, [step])`**

returns a stream that's a slice of the iterator. With a single *stop* argument, it will return the first *stop* elements. If you supply a starting index, you'll get *stop-start* elements, and if you supply a value for *step*, elements will be skipped accordingly. Unlike Python's string and list slicing, you can't use negative values for *start*, *stop*, or *step*.

```
itertools.islice(range(10), 8) =>
    0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) =>
    2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) =>
    2, 4, 6
```

**`itertools.tee(iter, [n])`** replicates an iterator; it returns *n* independent iterators that will all return the contents of the source iterator. If you don't supply a value for *n*, the default is 2. Replicating iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```
itertools.tee( itertools.count() ) =>
    iterA, iterB
```

```
where iterA ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

```
and iterB ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

## Calling functions on elements

The **`operator`** module contains a set of functions corresponding to Python's operators. Some examples are **`operator.add(a, b)`** (adds two values), **`operator.ne(a, b)`** (same as `a != b`), and **`operator.attrgetter('id')`** (returns a callable that fetches

the `.id` attribute).

**`itertools.starmap(func, iter)`** assumes that the iterable will return a stream of tuples, and calls *func* using these tuples as the arguments:

```
itertools.starmap(os.path.join,
                  [('/bin', 'python'), ('/usr', 'bin', 'python'),
                   ('/usr', 'bin', 'perl'), ('/usr', 'bin', 'ruby')])
=>
    /bin/python, /usr/bin/java, /usr/bin/perl, /usr/bin/ruby
```

## Selecting elements

Another group of functions chooses a subset of an iterator's elements based on a predicate.

**`itertools.filterfalse(predicate, iter)`** is the opposite of **`filter()`**, returning all elements for which the predicate returns false:

```
itertools.filterfalse(is_even, itertools.count()) =>
    1, 3, 5, 7, 9, 11, 13, 15, ...
```

**`itertools.takewhile(predicate, iter)`** returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```
def less_than_10(x):
    return x < 10
```

```
itertools.takewhile(less_than_10, itertools.count()) =>
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9
```

```
itertools.takewhile(is_even, itertools.count()) =>
    0
```

**`itertools.dropwhile(predicate, iter)`** discards elements while the predicate returns true, and then returns the rest of the iterable's results.

```
itertools.dropwhile(less_than_10, itertools.count()) =>
    10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...

itertools.dropwhile(is_even, itertools.count()) =>
    1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```

**`itertools.compress(data, selectors)`** takes two iterators and returns only those elements of *data* for which the corresponding element of *selectors* is true, stopping whenever either one is exhausted:

```
itertools.compress([1, 2, 3, 4, 5], [True, True, False,
    1, 2, 5
```

## Combinatoric functions

The **`itertools.combinations(iterable, r)`** returns an iterator giving all possible *r*-tuple combinations of the elements contained in *iterable*.

```
itertools.combinations([1, 2, 3, 4, 5], 2) =>
    (1, 2), (1, 3), (1, 4), (1, 5),
    (2, 3), (2, 4), (2, 5),
    (3, 4), (3, 5),
    (4, 5)
```

```
itertools.combinations([1, 2, 3, 4, 5], 3) =>
    (1, 2, 3), (1, 2, 4), (1, 2, 5), (1, 3, 4), (1, 3, 5),
    (2, 3, 4), (2, 3, 5), (2, 4, 5),
    (3, 4, 5)
```

The elements within each tuple remain in the same order as *iterable* returned them. For example, the number 1 is always before 2, 3, 4, or 5 in the examples above. A similar function, **`itertools.permutations(iterable, r=None)`**, removes this constraint on the order, returning all possible arrangements of length *r*:

```
itertools.permutations([1, 2, 3, 4, 5], 2) =>
    (1, 2), (1, 3), (1, 4), (1, 5),
```

```
(2, 1), (2, 3), (2, 4), (2, 5),  
(3, 1), (3, 2), (3, 4), (3, 5),  
(4, 1), (4, 2), (4, 3), (4, 5),  
(5, 1), (5, 2), (5, 3), (5, 4)
```

```
itertools.permutations([1, 2, 3, 4, 5]) =>  
    (1, 2, 3, 4, 5), (1, 2, 3, 5, 4), (1, 2, 4, 3, 5),  
    ...  
    (5, 4, 3, 2, 1)
```

If you don't supply a value for *r* the length of the iterable is used, meaning that all the elements are permuted.

Note that these functions produce all of the possible combinations by position and don't require that the contents of *iterable* are unique:

```
itertools.permutations('aba', 3) =>  
    ('a', 'b', 'a'), ('a', 'a', 'b'), ('b', 'a', 'a'),  
    ('b', 'a', 'a'), ('a', 'a', 'b'), ('a', 'b', 'a')
```

The identical tuple ('a', 'a', 'b') occurs twice, but the two 'a' strings came from different positions.

The

**`itertools.combinations_with_replacement(iterable, r)`** function relaxes a different constraint: elements can be repeated within a single tuple. Conceptually an element is selected for the first position of each tuple and then is replaced before the second element is selected.

```
itertools.combinations_with_replacement([1, 2, 3, 4, 5],  
    (1, 1), (1, 2), (1, 3), (1, 4), (1, 5),  
    (2, 2), (2, 3), (2, 4), (2, 5),  
    (3, 3), (3, 4), (3, 5),  
    (4, 4), (4, 5),  
    (5, 5))
```

## Grouping elements

The last function I'll discuss, `itertools.groupby(iter, key_func=None)`, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don't supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

```
city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'), ('Tuscaloosa', 'AL'),
             ('Anchorage', 'AK'), ('Nome', 'AK'),
             ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ'),
             ...
            ]
```

```
def get_state(city_state):
    return city_state[1]
```

```
itertools.groupby(city_list, get_state) =>
    ('AL', iterator-1),
    ('AK', iterator-2),
    ('AZ', iterator-3), ...
```

where

```
iterator-1 =>
    ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma', 'AL'), ...
iterator-2 =>
    ('Anchorage', 'AK'), ('Nome', 'AK')
iterator-3 =>
    ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ'), ...
```

`groupby()` assumes that the underlying iterable's contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.

## The functools module

The `functools` module contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the `functools.partial()` function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function `f(a, b, c)`; you may wish to create a new function `g(b, c)` that's equivalent to `f(1, b, c)`; you're filling in a value for one of `f()`'s parameters. This is called "partial function application".

The constructor for `partial()` takes the arguments `(function, arg1, arg2, ..., kwarg1=value1, kwarg2=value2)`. The resulting object is callable, so you can just call it to invoke `function` with the filled-in arguments.

Here's a small but realistic example:

```
import functools

def log(message, subsystem):
    """Write the contents of 'message' to the specified
    print('%s: %s' % (subsystem, message))
    ...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

`functools.reduce(func, iter, [initial_value])` cumulatively performs an operation on all the iterable's elements and, therefore, can't be applied to infinite iterables. *func* must be a function that takes two elements and returns a single value. `functools.reduce()` takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a `TypeError` exception is raised. If the initial value is supplied, it's used as a starting point and

`func(initial_value, A)` is the first calculation.

```
>>> import operator, functools
>>> functools.reduce(operator.concat, ['A', 'BB', 'C'])
'ABBC'
>>> functools.reduce(operator.concat, [])
Traceback (most recent call last):
...
TypeError: reduce() of empty sequence with no initial value
>>> functools.reduce(operator.mul, [1, 2, 3], 1)
6
>>> functools.reduce(operator.mul, [], 1)
1
```

If you use `operator.add()` with `functools.reduce()`, you'll add up all the elements of the iterable. This case is so common that there's a special built-in called `sum()` to compute it:

```
>>> import functools, operator
>>> functools.reduce(operator.add, [1, 2, 3, 4], 0)
10
>>> sum([1, 2, 3, 4])
10
>>> sum([])
0
```

For many uses of `functools.reduce()`, though, it can be clearer to just write the obvious `for` loop:

```
import functools
# Instead of:
product = functools.reduce(operator.mul, [1, 2, 3], 1)

# You can write:
product = 1
for i in [1, 2, 3]:
    product *= i
```

A related function is `itertools.accumulate(iterable, func=operator.add)`. It performs the same calculation, but

instead of returning only the final result, `accumulate()` returns an iterator that also yields each partial result:

```
itertools.accumulate([1, 2, 3, 4, 5]) =>  
1, 3, 6, 10, 15
```

```
itertools.accumulate([1, 2, 3, 4, 5], operator.mul) =>  
1, 2, 6, 24, 120
```

## The operator module

The `operator` module was mentioned earlier. It contains a set of functions corresponding to Python's operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:

- Math operations: `add()`, `sub()`, `mul()`, `floordiv()`, `abs()`, ...
- Logical operations: `not_()`, `truth()`.
- Bitwise operations: `and_()`, `or_()`, `invert()`.
- Comparisons: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- Object identity: `is_()`, `is_not()`.

Consult the operator module's documentation for a complete list.

## Small functions and the lambda expression

When writing functional-style programs, you'll often need little functions that act as predicates or that combine elements in some way.

If there's a Python built-in or a module function that's suitable, you don't need to define a new function at all:

```
stripped_lines = [line.strip() for line in lines]  
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn't exist, you need to write it. One way to write small functions is to use the `lambda` expression. `lambda` takes a number of parameters and an expression combining these parameters, and creates an anonymous function that returns the value of the expression:

```
adder = lambda x, y: x+y
```

```
print_assign = lambda name, value: name + '=' + str(value)
```

An alternative is to just use the `def` statement and define a function in the usual way:

```
def adder(x, y):  
    return x + y
```

```
def print_assign(name, value):  
    return name + '=' + str(value)
```

Which alternative is preferable? That's a style question; my usual course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can't have multiway `if...elif...else` comparisons or `try...except` statements. If

you try to do too much in a `lambda` statement, you'll end up with an overly complicated expression that's hard to read. Quick, what's the following code doing?

```
import functools  
total = functools.reduce(lambda a, b: (0, a[1] + b[1]),
```

You can figure it out, but it takes time to disentangle the expression to figure out what's going on. Using a short nested `def` statements makes things a little bit better:

```
import functools  
def combine(a, b):  
    return 0, a[1] + b[1]
```

```
total = functools.reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```
total = 0
for a, b in items:
    total += b
```

Or the `sum()` built-in and a generator expression:

```
total = sum(b for a, b in items)
```

Many uses of `functools.reduce()` are clearer when written as `for` loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of `lambda`:

1. Write a `lambda` function.
2. Write a comment explaining what the heck that `lambda` does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the `lambda` to a `def` statement, using that name.
5. Remove the comment.

I really like these rules, but you're free to disagree about whether this `lambda`-free style is better.

## Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged `genexp` and `listcomp`

sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the `functional` module written by Collin Winter; adds short section on the operator module; a few other edits.

# Logging HOWTO

## Author

Vinay Sajip <vinay\_sajip at red-dove dot com>

This page contains tutorial information. For links to reference information and a logging cookbook, please see [Other resources](#).

## Basic Logging Tutorial

Logging is a means of tracking events that happen when some software runs. The software's developer adds logging calls to their code to indicate that certain events have occurred. An event is described by a descriptive message which can optionally contain variable data (i.e. data that is potentially different for each occurrence of the event). Events also have an importance which the

developer ascribes to the event; the importance can also be called the *level* or *severity*.

## When to use logging

Logging provides a set of convenience functions for simple logging usage. These are `debug()`, `info()`, `warning()`, `error()` and `critical()`. To determine when to use logging, see the table below, which states, for each of a set of common tasks, the best tool to use for it.

### Task best tool for the task

---

<code>Display()</code>	console output for ordinary usage of a command line script or program
------------------------	-----------------------------------------------------------------------

---

<code>Report events that occur during normal operation of a program (e.g. for diagnostic purposes)</code>	<code>debug()</code> or <code>info()</code> (default investigation)
-----------------------------------------------------------------------------------------------------------	---------------------------------------------------------------------

---

<code>Issue a warning regarding a particular situation that is unavoidable and the client application should be modified to eliminate the warning</code>	<code>logging.warning()</code> if there is nothing the client application can do about the situation, but the event should still be noted
----------------------------------------------------------------------------------------------------------------------------------------------------------	-------------------------------------------------------------------------------------------------------------------------------------------

---

<code>Raise an exception regarding a particular runtime event</code>	<code>Report suppression of an error without raising an exception (e.g. error handler in a long-running service for the application domain)</code>
----------------------------------------------------------------------	----------------------------------------------------------------------------------------------------------------------------------------------------

---

The logging functions are named after the level or severity of the events they are used to track. The standard levels and their applicability are described below (in increasing order of severity):

### When it's used

---

<code>DEBUG</code>	Detailed information, typically of interest only when diagnosing problems.
--------------------	----------------------------------------------------------------------------

---

<code>INFO</code>	Confirmation that things are working as expected.
-------------------	---------------------------------------------------

---

<code>WARNING</code>	An indication that something unexpected happened, or indicative of some problem in the near future (e.g. 'disk space low'). The software is still working as expected.
----------------------	------------------------------------------------------------------------------------------------------------------------------------------------------------------------

---

<code>ERROR</code>	On a more serious problem, the software has not been able to perform some function.
--------------------	-------------------------------------------------------------------------------------

---

<code>CRITICAL</code>	A serious error, indicating that the program itself may be unable
-----------------------	-------------------------------------------------------------------

---

to continue running.

---

The default level is `WARNING`, which means that only events of this level and above will be tracked, unless the logging package is configured to do otherwise.

Events that are tracked can be handled in different ways. The simplest way of handling tracked events is to print them to the console. Another common way is to write them to a disk file.

## A simple example

A very simple example is:

```
import logging
logging.warning('Watch out!') # will print a message to the console
logging.info('I told you so') # will not print anything to the console
```

If you type these lines into a script and run it, you'll see:

```
WARNING:root:Watch out!
```

printed out on the console. The `INFO` message doesn't appear because the default level is `WARNING`. The printed message includes the indication of the level and the description of the event provided in the logging call, i.e. 'Watch out!'. Don't worry about the 'root' part for now: it will be explained later. The actual output can be formatted quite flexibly if you need that; formatting options will also be explained later.

## Logging to a file

A very common situation is that of recording logging events in a file, so let's look at that next. Be sure to try the following in a newly started Python interpreter, and don't just continue from the session described above:

```
import logging
logging.basicConfig(filename='example.log', encoding='utf-8')
logging.debug('This message should go to the log file')
logging.info('So should this')
```

```
logging.warning('And this, too')
logging.error('And non-ASCII stuff, too, like Øresund and Ma
```

*Changed in version 3.9:* The *encoding* argument was added. In earlier Python versions, or if not specified, the encoding used is the default value used by `open()`. While not shown in the above example, an *errors* argument can also now be passed, which determines how encoding errors are handled. For available values and the default, see the documentation for `open()`.

And now if we open the file and look at what we have, we should find the log messages:

```
DEBUG:root:This message should go to the log file
INFO:root:So should this
WARNING:root:And this, too
ERROR:root:And non-ASCII stuff, too, like Øresund and Ma
```

This example also shows how you can set the logging level which acts as the threshold for tracking. In this case, because we set the threshold to `DEBUG`, all of the messages were printed.

If you want to set the logging level from a command-line option such as:

```
--log=INFO
```

and you have the value of the parameter passed for `--log` in some variable *loglevel*, you can use:

```
getattr(logging, loglevel.upper())
```

to get the value which you'll pass to `basicConfig()` via the *level* argument. You may want to error check any user input value, perhaps as in the following example:

```
# assuming loglevel is bound to the string value obtained
# command line argument. Convert to upper case to allow
# specify --log=DEBUG or --log=debug
numeric_level = getattr(logging, loglevel.upper(), None)
if not isinstance(numeric_level, int):
```

```
        raise ValueError('Invalid log level: %s' % loglevel)
logging.basicConfig(level=numeric_level, ...)
```

The call to `basicConfig()` should come *before* any calls to `debug()`, `info()`, etc. Otherwise, those functions will call `basicConfig()` for you with the default options. As it's intended as a one-off simple configuration facility, only the first call will actually do anything: subsequent calls are effectively no-ops.

If you run the above script several times, the messages from successive runs are appended to the file *example.log*. If you want each run to start afresh, not remembering the messages from earlier runs, you can specify the *filemode* argument, by changing the call in the above example to:

```
logging.basicConfig(filename='example.log', filemode='w')
```

The output will be the same as before, but the log file is no longer appended to, so the messages from earlier runs are lost.

## Logging from multiple modules

If your program consists of multiple modules, here's an example of how you could organize logging in it:

```
# myapp.py
import logging
import mylib

def main():
    logging.basicConfig(filename='myapp.log', level=logging.INFO)
    logging.info('Started')
    mylib.do_something()
    logging.info('Finished')

if __name__ == '__main__':
    main()

# mylib.py
import logging
```

```
def do_something():  
    logging.info('Doing something')
```

If you run *myapp.py*, you should see this in *myapp.log*:

```
INFO:root:Started  
INFO:root:Doing something  
INFO:root:Finished
```

which is hopefully what you were expecting to see. You can generalize this to multiple modules, using the pattern in *mylib.py*. Note that for this simple usage pattern, you won't know, by looking in the log file, *where* in your application your messages came from, apart from looking at the event description. If you want to track the location of your messages, you'll need to refer to the documentation beyond the tutorial level – see [Advanced Logging Tutorial](#).

## Logging variable data

To log variable data, use a format string for the event description message and append the variable data as arguments. For example:

```
import logging  
logging.warning('%s before you %s', 'Look', 'leap!')
```

will display:

```
WARNING:root:Look before you leap!
```

As you can see, merging of variable data into the event description message uses the old, %-style of string formatting. This is for backwards compatibility: the logging package pre-dates newer formatting options such as `str.format()` and `string.Template`. These newer formatting options *are* supported, but exploring them is outside the scope of this tutorial: see [Using particular formatting styles throughout your application](#) for more information.

## Changing the format of displayed messages

To change the format which is used to display messages, you need to specify the format you want to use:

```
import logging
logging.basicConfig(format='%(levelname)s:%(message)s',
logging.debug('This message should appear on the console')
logging.info('So should this')
logging.warning('And this, too')
```

which would print:

```
DEBUG:This message should appear on the console
INFO:So should this
WARNING:And this, too
```

Notice that the ‘root’ which appeared in earlier examples has disappeared. For a full set of things that can appear in format strings, you can refer to the documentation for [LogRecord attributes](#), but for simple usage, you just need the *levelname* (severity), *message* (event description, including variable data) and perhaps to display when the event occurred. This is described in the next section.

## Displaying the date/time in messages

To display the date and time of an event, you would place ‘%(asctime)s’ in your format string:

```
import logging
logging.basicConfig(format='%(asctime)s %(message)s')
logging.warning('is when this event was logged.')
```

which should print something like this:

```
2010-12-12 11:41:42,612 is when this event was logged.
```

The default format for date/time display (shown above) is like ISO8601 or [RFC 3339](https://datatracker.ietf.org/doc/html/rfc3339.html) [https://datatracker.ietf.org/doc/html/rfc3339.html]. If you need more control over the formatting of the date/time, provide a *datefmt* argument to `basicConfig`, as in this example:

```
import logging
logging.basicConfig(format='%(asctime)s %(message)s', datefmt='%Y/%m/%d %H:%M:%S')
logging.warning('is when this event was logged.')
```

which would display something like this:

```
12/12/2010 11:46:36 AM is when this event was logged.
```

The format of the *datefmt* argument is the same as supported by `time.strftime()`.

## Next Steps

That concludes the basic tutorial. It should be enough to get you up and running with logging. There's a lot more that the logging package offers, but to get the best out of it, you'll need to invest a little more of your time in reading the following sections. If you're ready for that, grab some of your favourite beverage and carry on.

If your logging needs are simple, then use the above examples to incorporate logging into your own scripts, and if you run into problems or don't understand something, please post a question on the comp.lang.python Usenet group (available at <https://groups.google.com/g/comp.lang.python>) and you should receive help before too long.

Still here? You can carry on reading the next few sections, which provide a slightly more advanced/in-depth tutorial than the basic one above. After that, you can take a look at the [Logging Cookbook](#).

## Advanced Logging Tutorial

The logging library takes a modular approach and offers several categories of components: loggers, handlers, filters, and formatters.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which

log records to output.

- Formatters specify the layout of log records in the final output.

Log event information is passed between loggers, handlers, filters and formatters in a `LogRecord` instance.

Logging is performed by calling methods on instances of the `Logger` class (hereafter called *loggers*). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named 'scan' is the parent of loggers 'scan.text', 'scan.html' and 'scan.pdf'. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

A good convention to use when naming loggers is to use a module-level logger, in each module which uses logging, named as follows:

```
logger = logging.getLogger(__name__)
```

This means that logger names track the package/module hierarchy, and it's intuitively obvious where events are logged just from the logger name.

The root of the hierarchy of loggers is called the root logger. That's the logger used by the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, which just call the same-named method of the root logger. The functions and the methods have the same signatures. The root logger's name is printed as 'root' in the logged output.

It is, of course, possible to log messages to different destinations. Support is included in the package for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, queues, or OS-specific logging mechanisms such as syslog or the Windows NT event log. Destinations are served by *handler* classes. You can create your own log destination class if you have special requirements not met by any of the built-in handler classes.

By default, no destination is set for any logging messages. You can specify a destination (such as console or file) by using

`basicConfig()` as in the tutorial examples. If you call the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, they will check to see if no destination is set; and if one is not set, they will set a destination of the console (`sys.stderr`) and a default format for the displayed message before delegating to the root logger to do the actual message output.

The default format set by `basicConfig()` for messages is:

```
severity:logger name:message
```

You can change this by passing a format string to `basicConfig()` with the *format* keyword argument. For all options regarding how a format string is constructed, see [Formatter Objects](#).

## Logging Flow

The flow of log event information in loggers and handlers is illustrated in the following diagram.

## Loggers

**Logger** objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.

These are the most common configuration methods:

- `Logger.setLevel()` specifies the lowest-severity log message a logger will handle, where `debug` is the lowest built-in severity level and `critical` is the highest built-in severity. For example, if the severity level is `INFO`, the logger will handle only `INFO`, `WARNING`, `ERROR`, and `CRITICAL` messages and will ignore `DEBUG` messages.

- `Logger.addHandler()` and `Logger.removeHandler()` add and remove handler objects from the logger object. Handlers are covered in more detail in [Handlers](#).
- `Logger.addFilter()` and `Logger.removeFilter()` add and remove filter objects from the logger object. Filters are covered in more detail in [Filter Objects](#).

You don't need to always call these methods on every logger you create. See the last two paragraphs in this section.

With the logger object configured, the following methods create log messages:

- `Logger.debug()`, `Logger.info()`, `Logger.warning()`, `Logger.error()`, and `Logger.critical()` all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of `%s`, `%d`, `%f`, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to `**kwargs`, the logging methods care only about a keyword of `exc_info` and use it to determine whether to log exception information.
- `Logger.exception()` creates a log message similar to `Logger.error()`. The difference is that `Logger.exception()` dumps a stack trace along with it. Call this method only from an exception handler.
- `Logger.log()` takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

`getLogger()` returns a reference to a logger instance with the specified name if it is provided, or `root` if not. The names are period-separated hierarchical structures. Multiple calls to `getLogger()` with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and `foo.bam` are all descendants of

foo.

Loggers have a concept of *effective level*. If a level is not explicitly set on a logger, the level of its parent is used instead as its effective level. If the parent has no explicit level set, *its* parent is examined, and so on - all ancestors are searched until an explicitly set level is found. The root logger always has an explicit level set (WARNING by default). When deciding whether to process an event, the effective level of the logger is used to determine whether the event is passed to the logger's handlers.

Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed. (You can, however, turn off propagation by setting the *propagate* attribute of a logger to False.)

## Handlers

**Handler** objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. **Logger** objects can add zero or more handler objects to themselves with an **addHandler()** method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types (see [Useful Handlers](#)); the tutorials use mainly **StreamHandler** and **FileHandler** in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The `setLevel()` method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two `setLevel()` methods? The level set in the logger determines which severity of messages it will pass to its handlers. The level set in each handler determines which messages that handler will send on.
- `setFormatter()` selects a Formatter object for this handler to use.
- `addFilter()` and `removeFilter()` respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of `Handler`. Instead, the `Handler` class is a base class that defines the interface that all handlers should have and establishes some default behavior that child classes can use (or override).

## Formatters

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base `logging.Handler` class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes three optional arguments – a message format string, a date format string and a style indicator.

```
logging.Formatter._init_(fmt=None, datefmt=None, style='%')
```

If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end. The `style` is one of `'%'`, `'{'`, or `'$'`. If one of these is not specified, then `'%'` will be used.

If the `style` is `'%'`, the message format string uses `%( <dictionary key> )s` styled string substitution; the possible keys are documented in [LogRecord attributes](#). If the style is `'{'`, the message format string is assumed to be compatible with

`str.format()` (using keyword arguments), while if the style is `'$'` then the message format string should conform to what is expected by `string.Template.substitute()`.

*Changed in version 3.2:* Added the `style` parameter.

The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:

```
'%(asctime)s - %(levelname)s - %(message)s'
```

Formatters use a user-configurable function to convert the creation time of a record to a tuple. By default, `time.localtime()` is used; to change this for a particular formatter instance, set the `converter` attribute of the instance to a function with the same signature as `time.localtime()` or `time.gmtime()`. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the `converter` attribute in the `Formatter` class (to `time.gmtime` for GMT display).

## Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the `fileConfig()` function.
3. Creating a dictionary of configuration information and passing it to the `dictConfig()` function.

For the reference documentation on the last two options, see [Configuration functions](#). The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

```
import logging

# create logger
```

```
logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s')

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

**Running this module from the command line produces the following output:**

```
$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug message
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn message
2005-03-19 15:10:26,697 - simple_example - ERROR - error message
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical message
```

**The following Python module creates a logger, handler, and formatter nearly identical to those in the example listed above, with the only difference being the names of the objects:**

```
import logging
import logging.config
```

```
logging.config.fileConfig('logging.conf')

# create logger
logger = logging.getLogger('simpleExample')

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Here is the logging.conf file:

```
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter

[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
qualname=simpleExample
propagate=0

[handler_consoleHandler]
class=StreamHandler
level=DEBUG
formatter=simpleFormatter
args=(sys.stdout,)
```

```
[formatter_simpleFormatter]  
format=%(asctime)s - %(name)s - %(levelname)s - %(message)s
```

The output is nearly identical to that of the non-config-file-based example:

```
$ python simple_logging_config.py  
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug  
2005-03-19 15:38:55,979 - simpleExample - INFO - info message  
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn  
2005-03-19 15:38:56,055 - simpleExample - ERROR - error  
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - cri
```

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

## Warning

The `fileConfig()` function takes a default parameter, `disable_existing_loggers`, which defaults to `True` for reasons of backward compatibility. This may or may not be what you want, since it will cause any non-root loggers existing before the `fileConfig()` call to be disabled unless they (or an ancestor) are explicitly named in the configuration. Please refer to the reference documentation for more information, and specify `False` for this parameter if you wish.

The dictionary passed to `dictConfig()` can also specify a Boolean value with key `disable_existing_loggers`, which if not specified explicitly in the dictionary also defaults to being interpreted as `True`. This leads to the logger-disabling behaviour described above, which may not be what you want - in which case, provide the key explicitly with a value of `False`.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use

either `WatchedFileHandler` (relative to the logging module) or `mypackage.mymodule.MyHandler` (for a class defined in package `mypackage` and module `mymodule`, where `mypackage` is available on the Python import path).

In Python 3.2, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense for your application.

Here's an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```
version: 1
formatters:
  simple:
    format: '%(asctime)s - %(name)s - %(levelname)s - %(message)s'
handlers:
  console:
    class: logging.StreamHandler
    level: DEBUG
    formatter: simple
    stream: ext://sys.stdout
loggers:
  simpleExample:
    level: DEBUG
    handlers: [console]
    propagate: no
root:
  level: DEBUG
  handlers: [console]
```

For more information about logging using a dictionary, see [Configuration functions](#).

## What happens if no configuration is provided

If no logging configuration is provided, it is possible to have a situation where a logging event needs to be output, but no handlers can be found to output the event. The behaviour of the logging package in these circumstances is dependent on the Python version.

For versions of Python prior to 3.2, the behaviour is as follows:

- If `logging.raiseExceptions` is `False` (production mode), the event is silently dropped.
- If `logging.raiseExceptions` is `True` (development mode), a message ‘No handlers could be found for logger X.Y.Z’ is printed once.

In Python 3.2 and later, the behaviour is as follows:

- The event is output using a ‘handler of last resort’, stored in `logging.lastResort`. This internal handler is not associated with any logger, and acts like a [StreamHandler](#) which writes the event description message to the current value of `sys.stderr` (therefore respecting any redirections which may be in effect). No formatting is done on the message - just the bare event description message is printed. The handler’s level is set to `WARNING`, so all events at this and greater severities will be output.

To obtain the pre-3.2 behaviour, `logging.lastResort` can be set to `None`.

## Configuring Logging for a Library

When developing a library which uses logging, you should take care to document how the library uses logging - for example, the names of loggers used. Some consideration also needs to be given to its logging configuration. If the using application does not use logging, and library code makes logging calls, then (as described in the previous section) events of severity `WARNING` and greater will be

printed to `sys.stderr`. This is regarded as the best default behaviour.

If for some reason you *don't* want these messages printed in the absence of any logging configuration, you can attach a do-nothing handler to the top-level logger for your library. This avoids the message being printed, since a handler will always be found for the library's events: it just doesn't produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler is included in the logging package: **NullHandler** (since Python 3.1). An instance of this handler could be added to the top-level logger of the logging namespace used by the library (*if* you want to prevent your library's logged events being output to `sys.stderr` in the absence of logging configuration). If all logging by a library *foo* is done using loggers with names matching 'foo.x', 'foo.x.y', etc. then the code:

```
import logging
logging.getLogger('foo').addHandler(logging.NullHandler())
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be 'orgname.foo' rather than just 'foo'.

## Note

It is strongly advised that you *do not log to the root logger* in your library. Instead, use a logger with a unique and easily identifiable name, such as the `__name__` for your library's top-level package or module. Logging to the root logger will make it difficult or impossible for the application developer to configure the logging verbosity or handlers of your library as they wish.

## Note

It is strongly advised that you *do not add any handlers other than*

**NullHandler** to your library's loggers. This is because the configuration of handlers is the prerogative of the application developer who uses your library. The application developer knows their target audience and what handlers are most appropriate for their application: if you add handlers 'under the hood', you might well interfere with their ability to carry out unit tests and deliver logs which suit their requirements.

## Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

Numeric value
50
CRITICAL
40
ERROR
30
WARNING
20
INFO
10
DEBUG
0
NOTSET

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger's level is higher than the method call's, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the **LogRecord** class. When a logger decides to actually log an event, a **LogRecord** instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through the use of *handlers*, which are instances of subclasses of the **Handler** class. Handlers are responsible for ensuring that a logged message (in the form of a **LogRecord**) ends up in a particular

location (or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed `LogRecord` instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the `addHandler()` method of `Logger`). In addition to any handlers directly associated with a logger, *all handlers associated with all ancestors of the logger* are called to dispatch the message (unless the *propagate* flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler's level acts as a filter in the same way as a logger's level does. If a handler decides to actually dispatch an event, the `emit()` method is used to send the message to its destination. Most user-defined subclasses of `Handler` will need to override this `emit()`.

## Custom Levels

Defining your own levels is possible, but should not be necessary, as the existing levels have been chosen on the basis of practical experience. However, if you are convinced that you need custom levels, great care should be exercised when doing this, and it is possibly *a very bad idea to define custom levels if you are developing a library*. That's because if multiple library authors all define their own custom levels, there is a chance that the logging output from such multiple libraries used together will be difficult for the using developer to control and/or interpret, because a given numeric value might mean different things for different libraries.

## Useful Handlers

In addition to the base `Handler` class, many useful subclasses are provided:

1. `StreamHandler` instances send messages to streams (file-like objects).
2. `FileHandler` instances send messages to disk files.
3. `BaseRotatingHandler` is the base class for handlers that

rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use `RotatingFileHandler` or `TimedRotatingFileHandler`.

4. `RotatingFileHandler` instances send messages to disk files, with support for maximum log file sizes and log file rotation.
5. `TimedRotatingFileHandler` instances send messages to disk files, rotating the log file at certain timed intervals.
6. `SocketHandler` instances send messages to TCP/IP sockets. Since 3.4, Unix domain sockets are also supported.
7. `DatagramHandler` instances send messages to UDP sockets. Since 3.4, Unix domain sockets are also supported.
8. `SMTPHandler` instances send messages to a designated email address.
9. `SysLogHandler` instances send messages to a Unix syslog daemon, possibly on a remote machine.
10. `NTEventLogHandler` instances send messages to a Windows NT/2000/XP event log.
11. `MemoryHandler` instances send messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. `HTTPHandler` instances send messages to an HTTP server using either `GET` or `POST` semantics.
13. `WatchedFileHandler` instances watch the file they are logging to. If the file changes, it is closed and reopened using the file name. This handler is only useful on Unix-like systems; Windows does not support the underlying mechanism used.
14. `QueueHandler` instances send messages to a queue, such as those implemented in the `queue` or `multiprocessing` modules.
15. `NullHandler` instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the ‘No handlers could be found for logger XXX’ message which can be displayed if the library user has not configured logging. See [Configuring Logging for a Library](#) for more information.

*New in version 3.1:* The `NullHandler` class.

*New in version 3.2:* The `QueueHandler` class.

The `NullHandler`, `StreamHandler` and `FileHandler` classes are defined in the core logging package. The other handlers are defined in a sub-module, `logging.handlers`. (There is also another sub-module, `logging.config`, for configuration functionality.)

Logged messages are formatted for presentation through instances of the `Formatter` class. They are initialized with a format string suitable for use with the `%` operator and a dictionary.

For formatting multiple messages in a batch, instances of `BufferingFormatter` can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of `Filter` can be added to both `Logger` and `Handler` instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic `Filter` functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.

## Exceptions raised during logging

The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

`SystemExit` and `KeyboardInterrupt` exceptions are never swallowed. Other exceptions which occur during the `emit()` method of a `Handler` subclass are passed to its `handleError()` method.

The default implementation of `handleError()` in `Handler`

checks to see if a module-level variable, `raiseExceptions`, is set. If set, a traceback is printed to `sys.stderr`. If not set, the exception is swallowed.

### Note

The default value of `raiseExceptions` is `True`. This is because during development, you typically want to be notified of any exceptions that occur. It's advised that you set `raiseExceptions` to `False` for production usage.

## Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its `__str__()` method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the `SocketHandler` emits an event by pickling it and sending it over the wire.

## Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the `isEnabledFor()` method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```
if logger.isEnabledFor(logging.DEBUG):
    logger.debug('Message with %s, %s', expensive_func1(),
               expensive_func2())
```

so that if the logger's threshold is set above `DEBUG`, the calls to `expensive_func1()` and `expensive_func2()` are never made.

## Note

In some cases, `isEnabledFor()` can itself be more expensive than you'd like (e.g. for deeply nested loggers where an explicit level is only set high up in the logger hierarchy). In such cases (or if you want to avoid calling a method in tight loops), you can cache the result of a call to `isEnabledFor()` in a local or instance variable, and use that instead of calling the method each time. Such a cached value would only need to be recomputed when the logging configuration changes dynamically while the application is running (which is not all that common).

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here's a list of things you can do to avoid processing during logging which you don't need:

### What you can do to collect

---

Information about where calls were made avoids calling `sys._getframe()`, which may help to speed up your code in environments like PyPy (which can't speed up code that uses `sys._getframe()`).

---

Get thread information. Leads to `False`.

---

Get current process ID (or `os.getpid()`). `False`.

---

Get current process name when using `subprocess` or `subprocess.Popen` to manage multiple processes.

---

Get current `asyncio` task name when using `asyncio`.

---

Also note that the core logging module only includes the basic handlers. If you don't import `logging.handlers` and `logging.config`, they won't take up any memory.

This page contains a number of recipes related to logging, which have been found useful in the past. For links to tutorial and reference information, please see [Other resources](#).

## Using logging in multiple modules

Multiple calls to `logging.getLogger('someLogger')` return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```
import logging
import auxiliary_module

# create logger with 'spam_application'
logger = logging.getLogger('spam_application')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s -
```

```
fh.setFormatter(formatter)
ch.setFormatter(formatter)
# add the handlers to the logger
logger.addHandler(fh)
logger.addHandler(ch)

logger.info('creating an instance of auxiliary_module.Auxiliary')
a = auxiliary_module.Auxiliary()
logger.info('created an instance of auxiliary_module.Auxiliary')
logger.info('calling auxiliary_module.Auxiliary.do_something()')
a.do_something()
logger.info('finished auxiliary_module.Auxiliary.do_something()')
logger.info('calling auxiliary_module.some_function()')
auxiliary_module.some_function()
logger.info('done with auxiliary_module.some_function()')
```

**Here is the auxiliary module:**

```
import logging

# create logger
module_logger = logging.getLogger('spam_application.auxiliary')

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger('spam_application.auxiliary')
        self.logger.info('creating an instance of Auxiliary')

    def do_something(self):
        self.logger.info('doing something')
        a = 1 + 1
        self.logger.info('done doing something')

def some_function():
    module_logger.info('received a call to "some_function"')
```

**The output looks like this:**

```
2005-03-23 23:47:11,663 - spam_application - INFO -
```

```
creating an instance of auxiliary_module.Auxiliary

## Logging from multiple threads

Logging from multiple threads requires no special effort. The following example shows logging from the main (initial) thread and another thread:

```
import logging
import threading
import time

def worker(arg):
    while not arg['stop']:
        logging.debug('Hi from myfunc')
        time.sleep(0.5)

def main():
    logging.basicConfig(level=logging.DEBUG, format='%(asctime)s')
    info = {'stop': False}
```

```

thread = threading.Thread(target=worker, args=(info,
thread.start()
while True:
    try:
        logging.debug('Hello from main')
        time.sleep(0.75)
    except KeyboardInterrupt:
        info['stop'] = True
        break
thread.join()

if __name__ == '__main__':
    main()

```

When run, the script should print something like the following:

```

0 Thread-1 Hi from myfunc
3 MainThread Hello from main
505 Thread-1 Hi from myfunc
755 MainThread Hello from main
1007 Thread-1 Hi from myfunc
1507 MainThread Hello from main
1508 Thread-1 Hi from myfunc
2010 Thread-1 Hi from myfunc
2258 MainThread Hello from main
2512 Thread-1 Hi from myfunc
3009 MainThread Hello from main
3013 Thread-1 Hi from myfunc
3515 Thread-1 Hi from myfunc
3761 MainThread Hello from main
4017 Thread-1 Hi from myfunc
4513 MainThread Hello from main
4518 Thread-1 Hi from myfunc

```

This shows the logging output interspersed as one might expect. This approach works for more threads than shown here, of course.

## Multiple handlers and formatters

Loggers are plain Python objects. The `addHandler()` method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```
import logging

logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %s')
ch.setFormatter(formatter)
fh.setFormatter(formatter)
# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Notice that the ‘application’ code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named *fh*.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many `print` statements for debugging, use `logger.debug`: Unlike the `print` statements, which you will have to delete or comment out later, the `logger.debug` statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.

## Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of `DEBUG` and higher to file, and those messages at level `INFO` and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```
import logging

# set up logging to file - see previous section for more
logging.basicConfig(level=logging.DEBUG,
                    format='%(asctime)s %(name)-12s %(levelname)-8s',
                    datefmt='%m-%d %H:%M',
                    filename='/tmp/myapp.log',
                    filemode='w')

# define a Handler which writes INFO messages or higher
console = logging.StreamHandler()
console.setLevel(logging.INFO)
# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s: %(levelname)-8s %(message)s')
# tell the handler to use this format
console.setFormatter(formatter)
# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger
logging.info('Jackdaws love my big sphinx of quartz.')
```

```
# Now, define a couple of other loggers which might represent
# application:
```

```
logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')
```

```
logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')
```

When you run this, on the console you will see

```
root          : INFO          Jackdaws love my big sphinx of quartz.
myapp.area1   : INFO          How quickly daft jumping zebras vex.
myapp.area2   : WARNING       Jail zesty vixen who grabbed pay from quack.
myapp.area2   : ERROR         The five boxing wizards jump quickly.
```

and in the file you will see something like

```
10-22 22:19 root          INFO          Jackdaws love my big sphinx of quartz.
10-22 22:19 myapp.area1   DEBUG         Quick zephyrs blow, vexing daft Jim.
10-22 22:19 myapp.area1   INFO          How quickly daft jumping zebras vex.
10-22 22:19 myapp.area2   WARNING       Jail zesty vixen who grabbed pay from quack.
10-22 22:19 myapp.area2   ERROR         The five boxing wizards jump quickly.
```

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.

Note that the above choice of log filename `/tmp/myapp.log` implies use of a standard location for temporary files on POSIX systems. On Windows, you may need to choose a different directory name for the log - just ensure that the directory exists and that you have the permissions to create and update files in it.

## Custom handling of levels

Sometimes, you might want to do something slightly different from the standard handling of levels in handlers, where all levels above a threshold get processed by a handler. To do this, you need to use filters. Let's look at a scenario where you want to arrange things as follows:

- Send messages of severity `INFO` and `WARNING` to `sys.stdout`
- Send messages of severity `ERROR` and above to `sys.stderr`
- Send messages of severity `DEBUG` and above to file `app.log`

Suppose you configure logging with the following JSON:

```
{
  "version": 1,
  "disable_existing_loggers": false,
  "formatters": {
    "simple": {
      "format": "%(levelname)-8s - %(message)s"
    }
  },
  "handlers": {
    "stdout": {
      "class": "logging.StreamHandler",
      "level": "INFO",
      "formatter": "simple",
      "stream": "ext://sys.stdout"
    },
    "stderr": {
      "class": "logging.StreamHandler",
      "level": "ERROR",
      "formatter": "simple",
      "stream": "ext://sys.stderr"
    },
    "file": {
      "class": "logging.FileHandler",
      "formatter": "simple",
      "filename": "app.log",
```

```

        "mode": "w"
    }
},
"root": {
    "level": "DEBUG",
    "handlers": [
        "stderr",
        "stdout",
        "file"
    ]
}
}

```

This configuration does *almost* what we want, except that `sys.stdout` would show messages of severity `ERROR` and above as well as `INFO` and `WARNING` messages. To prevent this, we can set up a filter which excludes those messages and add it to the relevant handler. This can be configured by adding a `filters` section parallel to `formatters` and `handlers`:

```

{
    "filters": {
        "warnings_and_below": {
            "()" : "__main__.filter_maker",
            "level": "WARNING"
        }
    }
}

```

and changing the section on the `stdout` handler to add it:

```

{
    "stdout": {
        "class": "logging.StreamHandler",
        "level": "INFO",
        "formatter": "simple",
        "stream": "ext://sys.stdout",
        "filters": ["warnings_and_below"]
    }
}

```

```
}
```

A filter is just a function, so we can define the `filter_maker` (a factory function) as follows:

```
def filter_maker(level):
    level = getattr(logging, level)

    def filter(record):
        return record.levelno <= level

    return filter
```

This converts the string argument passed in to a numeric level, and returns a function which only returns `True` if the level of the passed in record is at or below the specified level. Note that in this example I have defined the `filter_maker` in a test script `main.py` that I run from the command line, so its module will be `__main__` - hence the `__main__.filter_maker` in the filter configuration. You will need to change that if you define it in a different module.

With the filter added, we can run `main.py`, which in full is:

```
import json
import logging
import logging.config

CONFIG = '''
{
    "version": 1,
    "disable_existing_loggers": false,
    "formatters": {
        "simple": {
            "format": "%(levelname)-8s - %(message)s"
        }
    },
    "filters": {
        "warnings_and_below": {
            "()" : "__main__.filter_maker",
```

```

        "level": "WARNING"
    }
},
"handlers": {
    "stdout": {
        "class": "logging.StreamHandler",
        "level": "INFO",
        "formatter": "simple",
        "stream": "ext://sys.stdout",
        "filters": ["warnings_and_below"]
    },
    "stderr": {
        "class": "logging.StreamHandler",
        "level": "ERROR",
        "formatter": "simple",
        "stream": "ext://sys.stderr"
    },
    "file": {
        "class": "logging.FileHandler",
        "formatter": "simple",
        "filename": "app.log",
        "mode": "w"
    }
},
"root": {
    "level": "DEBUG",
    "handlers": [
        "stderr",
        "stdout",
        "file"
    ]
}
'''

```

```

def filter_maker(level):
    level = getattr(logging, level)

```

```
def filter(record):
    return record.levelno <= level

return filter
```

```
logging.config.dictConfig(json.loads(CONFIG))
logging.debug('A DEBUG message')
logging.info('An INFO message')
logging.warning('A WARNING message')
logging.error('An ERROR message')
logging.critical('A CRITICAL message')
```

And after running it like this:

```
python main.py 2>stderr.log >stdout.log
```

We can see the results are as expected:

```
$ more *.log
:::::::::::::
app.log
:::::::::::::
DEBUG      - A DEBUG message
INFO       - An INFO message
WARNING    - A WARNING message
ERROR      - An ERROR message
CRITICAL   - A CRITICAL message
:::::::::::::
stderr.log
:::::::::::::
ERROR      - An ERROR message
CRITICAL   - A CRITICAL message
:::::::::::::
stdout.log
:::::::::::::
INFO       - An INFO message
WARNING    - A WARNING message
```

## Configuration server example

Here is an example of a module using the logging configuration server:

```
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig('logging.conf')

# create and start listener on port 9999
t = logging.config.listen(9999)
t.start()

logger = logging.getLogger('simpleExample')

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug('debug message')
        logger.info('info message')
        logger.warning('warn message')
        logger.error('error message')
        logger.critical('critical message')
        time.sleep(5)
except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
    t.join()
```

And here is a script that takes a filename and sends that file to the server, properly preceded with the binary-encoded length, as the new logging configuration:

```
#!/usr/bin/env python
import socket, sys, struct
```

```
with open(sys.argv[1], 'rb') as f:
    data_to_send = f.read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print('connecting...')
s.connect((HOST, PORT))
print('sending config...')
s.send(struct.pack('>L', len(data_to_send)))
s.send(data_to_send)
s.close()
print('complete')
```

## Dealing with handlers that block

Sometimes you have to get your logging handlers to do their work without blocking the thread you're logging from. This is common in web applications, though of course it also occurs in other scenarios.

A common culprit which demonstrates sluggish behaviour is the **SMTPHandler**: sending emails can take a long time, for a number of reasons outside the developer's control (for example, a poorly performing mail or network infrastructure). But almost any network-based handler can block: Even a **SocketHandler** operation may do a DNS query under the hood which is too slow (and this query can be deep in the socket library code, below the Python layer, and outside your control).

One solution is to use a two-part approach. For the first part, attach only a **QueueHandler** to those loggers which are accessed from performance-critical threads. They simply write to their queue, which can be sized to a large enough capacity or initialized with no upper bound to their size. The write to the queue will typically be accepted quickly, though you will probably need to catch the **queue.Full** exception as a precaution in your code. If you are a library developer who has performance-critical threads in their code, be sure to document this (together with a suggestion to attach only **QueueHandlers** to your loggers) for the benefit of other

developers who will use your code.

The second part of the solution is `QueueListener`, which has been designed as the counterpart to `QueueHandler`. A `QueueListener` is very simple: it's passed a queue and some handlers, and it fires up an internal thread which listens to its queue for `LogRecords` sent from `QueueHandlers` (or any other source of `LogRecords`, for that matter). The `LogRecords` are removed from the queue and passed to the handlers for processing.

The advantage of having a separate `QueueListener` class is that you can use the same instance to service multiple `QueueHandlers`. This is more resource-friendly than, say, having threaded versions of the existing handler classes, which would eat up one thread per handler for no particular benefit.

An example of using these two classes follows (imports omitted):

```
que = queue.Queue(-1) # no limit on size
queue_handler = QueueHandler(que)
handler = logging.StreamHandler()
listener = QueueListener(que, handler)
root = logging.getLogger()
root.addHandler(queue_handler)
formatter = logging.Formatter('%(threadName)s: %(message)s')
handler.setFormatter(formatter)
listener.start()
# The log output will display the thread which generated
# the event (the main thread) rather than the internal
# thread which monitors the internal queue. This is what
# you want to happen.
root.warning('Look out!')
listener.stop()
```

which, when run, will produce:

```
MainThread: Look out!
```

## Note

Although the earlier discussion wasn't specifically talking about async code, but rather about slow logging handlers, it should be noted that when logging from async code, network and even file handlers could lead to problems (blocking the event loop) because some logging is done from `asyncio` internals. It might be best, if any async code is used in an application, to use the above approach for logging, so that any blocking code runs only in the `QueueListener` thread.

*Changed in version 3.5:* Prior to Python 3.5, the `QueueListener` always passed every message received from the queue to every handler it was initialized with. (This was because it was assumed that level filtering was all done on the other side, where the queue is filled.) From 3.5 onwards, this behaviour can be changed by passing a keyword argument `respect_handler_level=True` to the listener's constructor. When this is done, the listener compares the level of each message with the handler's level, and only passes a message to a handler if it's appropriate to do so.

## Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',
  logging.handlers.DEFAULT_TCP_LOGGING_PORT)
# don't bother with a formatter, since a socket handler
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger
```

```

logging.info('Jackdaws love my big sphinx of quartz.')

# Now, define a couple of other loggers which might represent
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')

```

At the receiving end, you can set up a receiver using the [socketserver](#) module. Here is a basic working example:

```

import pickle
import logging
import logging.handlers
import socketserver
import struct

class LogRecordStreamHandler(socketserver.StreamRequestHandler):
    """Handler for a streaming logging request.

    This basically logs the record using whatever logging
    configuration is locally.
    """

    def handle(self):
        """
        Handle multiple requests - each expected to be a
        LogRecord in pickle format. Logs each record
        according to whatever policy is configured locally.
        """
        while True:
            chunk = self.connection.recv(4)
            if len(chunk) < 4:

```

```

        break
    slen = struct.unpack('>L', chunk)[0]
    chunk = self.connection.recv(slen)
    while len(chunk) < slen:
        chunk = chunk + self.connection.recv(slen - len(chunk))
    obj = self.unPickle(chunk)
    record = logging.makeLogRecord(obj)
    self.handleLogRecord(record)

def unPickle(self, data):
    return pickle.loads(data)

def handleLogRecord(self, record):
    # if a name is specified, we use the named logger
    # implied by the record.
    if self.server.logname is not None:
        name = self.server.logname
    else:
        name = record.name
    logger = logging.getLogger(name)
    # N.B. EVERY record gets logged. This is because
    # is normally called AFTER logger-level filtering
    # to do filtering, do it at the client end to save
    # cycles and network bandwidth!
    logger.handle(record)

class LogRecordSocketReceiver(socketserver.ThreadingTCPServer):
    """
    Simple TCP socket-based logging receiver suitable for
    """

    allow_reuse_address = True

    def __init__(self, host='localhost',
                  port=logging.handlers.DEFAULT_TCP_LOGGING_PORT,
                  handler=LogRecordStreamHandler):
        socketserver.ThreadingTCPServer.__init__(self, (host, port))
        self.abort = 0

```

```

        self.timeout = 1
        self.logname = None

    def serve_until_stopped(self):
        import select
        abort = 0
        while not abort:
            rd, wr, ex = select.select([self.socket.file
  ], [], [],
  self.timeout)

            if rd:
                self.handle_request()
        abort = self.abort

def main():
    logging.basicConfig(
        format='%(relativeCreated)5d %(name)-15s %(levelname)s %s',
        tcpserver = LogRecordSocketReceiver()
    print('About to start TCP server...')
    tcpserver.serve_until_stopped()

if __name__ == '__main__':
    main()

```

First run the server, and then the client. On the client side, nothing is printed on the console; on the server side, you should see something like:

```

About to start TCP server...
59 root          INFO          Jackdaws love my big sph
59 myapp.area1    DEBUG          Quick zephyrs blow, vexir
69 myapp.area1    INFO          How quickly daft jumping
69 myapp.area2    WARNING        Jail zesty vixen who grab
69 myapp.area2    ERROR          The five boxing wizards j

```

Note that there are some security issues with pickle in some scenarios. If these affect you, you can use an alternative serialization scheme by overriding the `makePickle()` method and implementing your alternative there, as well as adapting the above

script to use your alternative serialization.

## Running a logging socket listener in production

To run a logging listener in production, you may need to use a process-management tool such as [Supervisor](http://supervisord.org/) [http://supervisord.org/].

[Here is a Gist](https://gist.github.com/vsajip/4b227ecec43817465ca835ca66f75e2b) [https://gist.github.com/vsajip/4b227ecec43817465ca835ca66f75e2b] which provides the bare-bones files to run the above functionality using Supervisor. It consists of the following files:

### File

---

A **Bash script** to prepare the environment for testing

---

The **Supervisor configuration file**, which has entries for the listener and a multi-process web application

---

A **Bash script** to ensure that Supervisor is running with the above configuration

---

The **socket listener program** which receives log events and records them to a file

---

A **simple web application** which performs logging via a socket connected to the listener

---

A **JSON configuration file** for the web application

---

A **Python script** to exercise the web application

---

The web application uses [Gunicorn](https://gunicorn.org/) [https://gunicorn.org/], which is a popular web application server that starts multiple worker processes to handle requests. This example setup shows how the workers can write to the same log file without conflicting with one another — they all go through the socket listener.

To test these files, do the following in a POSIX environment:

1. Download [the Gist](https://gist.github.com/vsajip/4b227ecec43817465ca835ca66f75e2b) [https://gist.github.com/vsajip/4b227ecec43817465ca835ca66f75e2b] as a ZIP archive using the *Download ZIP* button.
2. Unzip the above files from the archive into a scratch directory.
3. In the scratch directory, run `bash prepare.sh` to get things ready. This creates a `run` subdirectory to contain Supervisor-related and log files, and a `venv` subdirectory to contain a virtual environment into which `bottle`,

- unicorn and supervisor are installed.
4. Run `bash ensure_app.sh` to ensure that Supervisor is running with the above configuration.
  5. Run `venv/bin/python client.py` to exercise the web application, which will lead to records being written to the log.
  6. Inspect the log files in the `run` subdirectory. You should see the most recent log lines in files matching the pattern `app.log*`. They won't be in any particular order, since they have been handled concurrently by different worker processes in a non-deterministic way.
  7. You can shut down the listener and the web application by running `venv/bin/supervisorctl -c supervisor.conf shutdown`.

You may need to tweak the configuration files in the unlikely event that the configured ports clash with something else in your test environment.

## Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client's username, or IP address). Although you could use the *extra* parameter to achieve this, it's not always convenient to pass the information in this way. While it might be tempting to create **Logger** instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of **Logger** instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of **Logger** instances becomes effectively unbounded.

## Using LoggerAdapters to impart contextual information

An easy way in which you can pass contextual information to be output along with logging event information is to use the `LoggerAdapter` class. This class is designed to look like a `Logger`, so that you can call `debug()`, `info()`, `warning()`, `error()`, `exception()`, `critical()` and `log()`. These methods have the same signatures as their counterparts in `Logger`, so you can use the two types of instances interchangeably.

When you create an instance of `LoggerAdapter`, you pass it a `Logger` instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance of `LoggerAdapter`, it delegates the call to the underlying instance of `Logger` passed to its constructor, and arranges to pass the contextual information in the delegated call. Here's a snippet from the code of `LoggerAdapter`:

```
def debug(self, msg, /, *args, **kwargs):
    """
    Delegate a debug call to the underlying logger, after
    contextual information from this adapter instance.
    """
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)
```

The `process()` method of `LoggerAdapter` is where the contextual information is added to the logging output. It's passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an 'extra' key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an 'extra' keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using 'extra' is that the values in the dict-like object are merged into the `LogRecord` instance's `_dict_`, allowing you to use customized strings with your `Formatter` instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to

subclass `LoggerAdapter` and override `process()` to do what you need. Here is a simple example:

```
class CustomAdapter(logging.LoggerAdapter):
    """
    This example adapter expects the passed in dict-like
    'connid' key, whose value in brackets is prepended to
    """
    def process(self, msg, kwargs):
        return ' [%s] %s' % (self.extra['connid'], msg),
```

which you can use like this:

```
logger = logging.getLogger(__name__)
adapter = CustomAdapter(logger, {'connid': some_conn_id})
```

Then any events that you log to the adapter will have the value of `some_conn_id` prepended to the log messages.

## Using objects other than dicts to pass contextual information

You don't need to pass an actual dict to a `LoggerAdapter` - you could pass an instance of a class which implements `__getitem__` and `__iter__` so that it looks like a dict to logging. This would be useful if you want to generate values dynamically (whereas the values in a dict would be constant).

## Using Filters to impart contextual information

You can also add contextual information to log output using a user-defined `Filter`. Filter instances are allowed to modify the `LogRecords` passed to them, including adding additional attributes which can then be output using a suitable format string, or if needed a custom `Formatter`.

For example in a web application, the request being processed (or at least, the interesting parts of it) can be stored in a threadlocal (`threading.local`) variable, and then accessed from a `Filter` to add, say, information from the request - say, the remote IP address and remote user's username - to the `LogRecord`, using the

attribute names 'ip' and 'user' as in the `LoggerAdapter` example above. In that case, the same format string can be used to get similar output to that shown above. Here's an example script:

```
import logging
from random import choice

class ContextFilter(logging.Filter):
    """
    This is a filter which injects contextual information into log messages.

    Rather than use actual contextual information, we just use random
    data in this demo.
    """

    USERS = ['jim', 'fred', 'sheila']
    IPS = ['123.231.231.123', '127.0.0.1', '192.168.0.1']

    def filter(self, record):

        record.ip = choice(ContextFilter.IPS)
        record.user = choice(ContextFilter.USERS)
        return True

if __name__ == '__main__':
    levels = (logging.DEBUG, logging.INFO, logging.WARNING, logging.ERROR)
    logging.basicConfig(level=logging.DEBUG,
                        format='%(asctime)-15s %(name)-5s %(levelname)-8s %(message)s')

    a1 = logging.getLogger('a.b.c')
    a2 = logging.getLogger('d.e.f')

    f = ContextFilter()
    a1.addFilter(f)
    a2.addFilter(f)
    a1.debug('A debug message')
    a1.info('An info message with %s', 'some parameters')
    for x in range(10):
        lvl = choice(levels)
        lvlname = logging.getLevelName(lvl)
```

```
a2.log(lvl, 'A message at %s level with %d %s',
```

which, when run, produces something like:

```
2010-09-06 22:38:15,292 a.b.c DEBUG      IP: 123.231.231.1

```

## Use of `contextvars`

Since Python 3.7, the `contextvars` module has provided context-local storage which works for both `threading` and `asyncio` processing needs. This type of storage may thus be generally preferable to thread-locals. The following example shows how, in a multi-threaded environment, logs can be populated with contextual information such as, for example, request attributes handled by web applications.

For the purposes of illustration, say that you have different web applications, each independent of the other but running in the same Python process and using a library common to them. How can each of these applications have their own log, where all logging messages from the library (and other request processing code) are directed to the appropriate application's log file, while including in the log additional contextual information such as client IP, HTTP request method and client username?

Let's assume that the library can be simulated by the following code:

```
# webapplib.py
```

```

import logging
import time

logger = logging.getLogger(__name__)

def useful():
    # Just a representative event logged from the library
    logger.debug('Hello from webapplib!')
    # Just sleep for a bit so other threads get to run
    time.sleep(0.01)

```

We can simulate the multiple web applications by means of two simple classes, `Request` and `WebApp`. These simulate how real threaded web applications work - each request is handled by a thread:

```

# main.py
import argparse
from contextvars import ContextVar
import logging
import os
from random import choice
import threading
import webapplib

logger = logging.getLogger(__name__)
root = logging.getLogger()
root.setLevel(logging.DEBUG)

class Request:
    """
    A simple dummy request class which just holds dummy
    client IP address and client username
    """
    def __init__(self, method, ip, user):
        self.method = method
        self.ip = ip
        self.user = user

```

```
# A dummy set of requests which will be used in the simulation
# from this list randomly. Note that all GET requests are from
# addresses, whereas POST requests are from 192.16.3.XXX
# are represented in the sample requests.
```

```
REQUESTS = [
    Request('GET', '192.168.2.20', 'jim'),
    Request('POST', '192.168.3.20', 'fred'),
    Request('GET', '192.168.2.21', 'sheila'),
    Request('POST', '192.168.3.21', 'jim'),
    Request('GET', '192.168.2.22', 'fred'),
    Request('POST', '192.168.3.22', 'sheila'),
]
```

```
# Note that the format string includes references to request
# such as HTTP method, client IP and username
```

```
formatter = logging.Formatter('%(threadName)-11s %(appname)s %(message)s')
```

```
# Create our context variables. These will be filled at the start of
# processing, and used in the logging that happens during processing.
```

```
ctx_request = ContextVar('request')
ctx_appname = ContextVar('appname')
```

```
class InjectingFilter(logging.Filter):
    """
    A filter which injects context-specific information into log records.
    that only information for a specific webapp is included.
    """
    def __init__(self, app):
        self.app = app

    def filter(self, record):
        request = ctx_request.get()
        record.method = request.method
        record.ip = request.ip
        record.user = request.user
```

```

        record.appName = appName = ctx_appname.get()
        return appName == self.app.name

```

```

class WebApp:

```

```

    """

```

```

    A dummy web application class which has its own hand
    webapp-specific log.

```

```

    """

```

```

    def __init__(self, name):

```

```

        self.name = name

```

```

        handler = logging.FileHandler(name + '.log', 'w')

```

```

        f = InjectingFilter(self)

```

```

        handler.setFormatter(formatter)

```

```

        handler.addFilter(f)

```

```

        root.addHandler(handler)

```

```

        self.num_requests = 0

```

```

    def process_request(self, request):

```

```

        """

```

```

        This is the dummy method for processing a request
        different thread for every request. We store the
        the context vars before doing anything else.

```

```

        """

```

```

        ctx_request.set(request)

```

```

        ctx_appname.set(self.name)

```

```

        self.num_requests += 1

```

```

        logger.debug('Request processing started')

```

```

        webapplib.useful()

```

```

        logger.debug('Request processing finished')

```

```

def main():

```

```

    fn = os.path.splitext(os.path.basename(__file__))[0]

```

```

    adhf = argparse.ArgumentDefaultsHelpFormatter

```

```

    ap = argparse.ArgumentParser(formatter_class=adhf, p

```

```

                                description='Simulate a

```

```

                                'applicatio

```

```

                                'requests,

```

```

                                'context ca

```

'populate 1

```
aa = ap.add_argument
aa('--count', '-c', type=int, default=100, help='How
options = ap.parse_args()
```

```
# Create the dummy webapps and put them in a list wh
# from randomly
app1 = WebApp('app1')
app2 = WebApp('app2')
apps = [app1, app2]
threads = []
# Add a common handler which will capture all events
handler = logging.FileHandler('app.log', 'w')
handler.setFormatter(formatter)
root.addHandler(handler)
```

```
# Generate calls to process requests
for i in range(options.count):
    try:
        # Pick an app at random and a request for it
        app = choice(apps)
        request = choice(REQUESTS)
        # Process the request in its own thread
        t = threading.Thread(target=app.process_requ
        threads.append(t)
        t.start()
    except KeyboardInterrupt:
        break
```

```
# Wait for the threads to terminate
for t in threads:
    t.join()
```

```
for app in apps:
    print('%s processed %s requests' % (app.name, ap
```

```
if __name__ == '__main__':
    main()
```

If you run the above, you should find that roughly half the requests go into `app1.log` and the rest into `app2.log`, and the all the requests are logged to `app.log`. Each webapp-specific log will contain only log entries for only that webapp, and the request information will be displayed consistently in the log (i.e. the information in each dummy request will always appear together in a log line). This is illustrated by the following shell output:

```
~/logging-contextual-webapp$ python main.py
app1 processed 51 requests
app2 processed 49 requests
~/logging-contextual-webapp$ wc -l *.log
 153 app1.log
 147 app2.log
 300 app.log
 600 total

147
```

## Imparting contextual information in handlers

Each **Handler** has its own chain of filters. If you want to add contextual information to a **LogRecord** without leaking it to other handlers, you can use a filter that returns a new **LogRecord** instead of modifying it in-place, as shown in the following script:

```
import copy
import logging

def filter(record: logging.LogRecord):
    record = copy.copy(record)
    record.user = 'jim'
    return record

if __name__ == '__main__':
    logger = logging.getLogger()
    logger.setLevel(logging.INFO)
    handler = logging.StreamHandler()
    formatter = logging.Formatter('%(message)s from %(user)s')
    handler.setFormatter(formatter)
    handler.addFilter(filter)
    logger.addHandler(handler)

    logger.info('A log message')
```

## Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process is supported, logging to a single

file from *multiple processes* is *not* supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple processes, one way of doing this is to have all the processes log to a [SocketHandler](#), and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) [This section](#) documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

You could also write your own handler which uses the [Lock](#) class from the [multiprocessing](#) module to serialize access to the file from your processes. The existing [FileHandler](#) and subclasses do not make use of [multiprocessing](#) at present, though they may do so in the future. Note that at present, the [multiprocessing](#) module does not provide working lock functionality on all platforms (see <https://bugs.python.org/issue3770>).

Alternatively, you can use a [Queue](#) and a [QueueHandler](#) to send all logging events to one of the processes in your multi-process application. The following example script demonstrates how you can do this; in the example a separate listener process listens for events sent by other processes and logs them according to its own logging configuration. Although the example only demonstrates one way of doing it (for example, you may want to use a listener thread rather than a separate listener process – the implementation would be analogous) it does allow for completely different logging configurations for the listener and the other processes in your application, and can be used as the basis for code meeting your own specific requirements:

```
# You'll need these imports in your own code
import logging
import logging.handlers
import multiprocessing

# Next two import lines for this demo only
from random import choice, random
import time
```

```

#
# Because you'll want to define the logging configuration
# listener and worker process functions take a configured
# for configuring logging for that process. These functions
# which they use for communication.
#
# In practice, you can configure the listener however you want.
# simple example, the listener does not apply level or filter.
# In practice, you would probably want to do this logic in the
# sending events which would be filtered out between processes.
#
# The size of the rotated files is made small so you can rotate
def listener_configurer():
    root = logging.getLogger()
    h = logging.handlers.RotatingFileHandler('mptest.log')
    f = logging.Formatter('%(asctime)s %(processName)-10s %(message)s')
    h.setFormatter(f)
    root.addHandler(h)

# This is the listener process top-level loop: wait for
# (LogRecords) on the queue and handle them, quit when you get
# LogRecord.
def listener_process(queue, configurer):
    configurer()
    while True:
        try:
            record = queue.get()
            if record is None: # We send this as a sentinel
                break
            logger = logging.getLogger(record.name)
            logger.handle(record) # No level or filter
        except Exception:
            import sys, traceback
            print('Whoops! Problem:', file=sys.stderr)
            traceback.print_exc(file=sys.stderr)

# Arrays used for random selections in this demo

```

```
LEVELS = [logging.DEBUG, logging.INFO, logging.WARNING,
          logging.ERROR, logging.CRITICAL]
```

```
LOGGERS = ['a.b.c', 'd.e.f']
```

```
MESSAGES = [
    'Random message #1',
    'Random message #2',
    'Random message #3',
]
```

```
# The worker configuration is done at the start of the w
# Note that on Windows you can't rely on fork semantics,
# will run the logging configuration code when it starts
```

```
def worker_configurer(queue):
    h = logging.handlers.QueueHandler(queue) # Just the
    root = logging.getLogger()
    root.addHandler(h)
    # send all messages, for demo; no other level or fil
    root.setLevel(logging.DEBUG)
```

```
# This is the worker process top-level loop, which just
# random intervening delays before terminating.
# The print messages are just so you know it's doing som
```

```
def worker_process(queue, configurer):
    configurer(queue)
    name = multiprocessing.current_process().name
    print('Worker started: %s' % name)
    for i in range(10):
        time.sleep(random())
        logger = logging.getLogger(choice(LOGGERS))
        level = choice(LEVELS)
        message = choice(MESSAGES)
        logger.log(level, message)
    print('Worker finished: %s' % name)
```

```
# Here's where the demo gets orchestrated. Create the qu
```

```

# the listener, create ten workers and start them, wait
# then send a None to the queue to tell the listener to
def main():
    queue = multiprocessing.Queue(-1)
    listener = multiprocessing.Process(target=listener_p
                                      args=(queue, list

    listener.start()
    workers = []
    for i in range(10):
        worker = multiprocessing.Process(target=worker_p
                                      args=(queue, wo

        workers.append(worker)
        worker.start()
    for w in workers:
        w.join()
    queue.put_nowait(None)
    listener.join()

if __name__ == '__main__':
    main()

```

A variant of the above script keeps the logging in the main process, in a separate thread:

```

import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue
import random
import threading
import time

def logger_thread(q):
    while True:
        record = q.get()
        if record is None:
            break
        logger = logging.getLogger(record.name)
        logger.handle(record)

```

```

def worker_process(q):
    qh = logging.handlers.QueueHandler(q)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(qh)
    levels = [logging.DEBUG, logging.INFO, logging.WARNING,
               logging.CRITICAL]
    loggers = ['foo', 'foo.bar', 'foo.bar.baz',
               'spam', 'spam.ham', 'spam.ham.eggs']
    for i in range(100):
        lvl = random.choice(levels)
        logger = logging.getLogger(random.choice(loggers))
        logger.log(lvl, 'Message no. %d', i)

if __name__ == '__main__':
    q = Queue()

            },
            'foofile': {

```

```

        'class': 'logging.FileHandler',
        'filename': 'mplog-foo.log',
        'mode': 'w',
        'formatter': 'detailed',
    },
    'errors': {
        'class': 'logging.FileHandler',
        'filename': 'mplog-errors.log',
        'mode': 'w',
        'level': 'ERROR',
        'formatter': 'detailed',
    },
},
'loggers': {
    'foo': {
        'handlers': ['foofile']
    }
},
'root': {
    'level': 'DEBUG',
    'handlers': ['console', 'file', 'errors']
},
}

workers = []
for i in range(5):
    wp = Process(target=worker_process, name='worker' + str(i))
    workers.append(wp)
    wp.start()

logging.config.dictConfig(d)
lp = threading.Thread(target=logger_thread, args=(q,))
lp.start()
# At this point, the main process could do some useful work
# Once it's done that, it can wait for the workers to finish
for wp in workers:
    wp.join()
# And now tell the logging thread to finish up, too
q.put(None)
lp.join()

```

This variant shows how you can e.g. apply configuration for particular loggers - e.g. the `foo` logger has a special handler which stores all events in the `foo` subsystem in a file `mplog-foo.log`. This will be used by the logging machinery in the main process (even though the logging events are generated in the worker processes) to direct the messages to the appropriate destinations.

## Using `concurrent.futures.ProcessPoolExecutor`

If you want to use

`concurrent.futures.ProcessPoolExecutor` to start your worker processes, you need to create the queue slightly differently. Instead of

```
queue = multiprocessing.Queue(-1)
```

you should use

```
queue = multiprocessing.Manager().Queue(-1) # also works
```

and you can then replace the worker creation from this:

```
workers = []
for i in range(10):
    worker = multiprocessing.Process(target=worker_process,
                                     args=(queue, worker_id))
    workers.append(worker)
    worker.start()
for w in workers:
    w.join()
```

to this (remembering to first import `concurrent.futures`):

```
with concurrent.futures.ProcessPoolExecutor(max_workers=10):
    for i in range(10):
        executor.submit(worker_process, queue, worker_id)
```

## Deploying Web applications using Gunicorn and uWSGI

When deploying Web applications using [Gunicorn](https://gunicorn.org/) [https://gunicorn.org/] or [uWSGI](https://uwsgi-docs.readthedocs.io/en/latest/) [https://uwsgi-docs.readthedocs.io/en/latest/] (or similar), multiple worker processes are created to handle client requests. In such environments, avoid creating file-based handlers directly in your web application. Instead, use a [SocketHandler](#) to log from the web application to a listener in a separate process. This can be set up using a process management tool such as Supervisor - see [Running a logging socket listener in production](#) for more details.

## Using file rotation

Sometimes you want to let a log file grow to a certain size, then open a new file and log to that. You may want to keep a certain number of these files, and when that many files have been created, rotate the files so that the number of files and the size of the files both remain bounded. For this usage pattern, the logging package provides a [RotatingFileHandler](#):

```
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
    LOG_FILENAME, maxBytes=20, backupCount=5)

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)
```

```
# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print(filename)
```

The result should be 6 separate files, each with part of the log history for the application:

```
logging_rotatingfile_example.out
logging_rotatingfile_example.out.1
logging_rotatingfile_example.out.2
logging_rotatingfile_example.out.3
logging_rotatingfile_example.out.4
logging_rotatingfile_example.out.5
```

The most current file is always

`logging_rotatingfile_example.out`, and each time it reaches the size limit it is renamed with the suffix `.1`. Each of the existing backup files is renamed to increment the suffix (`.1` becomes `.2`, etc.) and the `.6` file is erased.

Obviously this example sets the log length much too small as an extreme example. You would want to set *maxBytes* to an appropriate value.

## Use of alternative formatting styles

When logging was added to the Python standard library, the only way of formatting messages with variable content was to use the %-formatting method. Since then, Python has gained two new formatting approaches: `string.Template` (added in Python 2.4) and `str.format()` (added in Python 2.6).

Logging (as of 3.2) provides improved support for these two additional formatting styles. The `Formatter` class been enhanced to take an additional, optional keyword parameter named `style`. This defaults to `'%'`, but other possible values are `'{'` and `'$'`, which correspond to the other two formatting styles. Backwards compatibility is maintained by default (as you would expect), but

by explicitly specifying a style parameter, you get the ability to specify format strings which work with `str.format()` or `string.Template`. Here's an example console session to show the possibilities:

```
>>> import logging
>>> root = logging.getLogger()
>>> root.setLevel(logging.DEBUG)
>>> handler = logging.StreamHandler()
>>> bf = logging.Formatter('{asctime} {name} {levelname}:
...                               style='{')
>>> handler.setFormatter(bf)
>>> root.addHandler(handler)
>>> logger = logging.getLogger('foo.bar')
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:11:55,341 foo.bar DEBUG      This is a DEBUG
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:12:11,526 foo.bar CRITICAL This is a CRITI
>>> df = logging.Formatter('$asctime $name ${levelname}
...                               style='$')
>>> handler.setFormatter(df)
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:13:06,924 foo.bar DEBUG This is a DEBUG me
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:13:11,494 foo.bar CRITICAL This is a CRITI
>>>
```

Note that the formatting of logging messages for final output to logs is completely independent of how an individual logging message is constructed. That can still use %-formatting, as shown here:

```
>>> logger.error('This is an%s %s %s', 'other,', 'ERROR,
2010-10-28 15:19:29,833 foo.bar ERROR This is another, E
>>>
```

Logging calls (`logger.debug()`, `logger.info()` etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the actual logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged,

or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using `str.format()` or `string.Template` syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would be no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There is, however, a way that you can use {}- and \$- formatting to construct your individual log messages. Recall that for a message you can use an arbitrary object as a message format string, and that the logging package will call `str()` on that object to get the actual format string. Consider the following two classes:

```
class BraceMessage:
    def __init__(self, fmt, /, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs)

class DollarMessage:
    def __init__(self, fmt, /, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwargs)
```

Either of these can be used in place of a format string, to allow {}- or \$-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “\$message”. It’s a little unwieldy to use the class names whenever you want to log something, but it’s quite palatable if you use an alias such as `_` (double underscore — not to be confused with `_`, the single underscore used as a synonym/alias for

`gettext.gettext()` or its brethren).

The above classes are not included in Python, though they're easy enough to copy and paste into your own code. They can be used as follows (assuming that they're declared in a module called `wherever`):

```
>>> from wherever import BraceMessage as __
>>> print(__('Message with {0} {name}', 2, name='placeholder'))
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f}, {point.y:.2f})',
...         point=p))
Message with coordinates: (0.50, 0.50)
>>> from wherever import DollarMessage as __
>>> print(__('Message with $num $what', num=2, what='placeholder'))
Message with 2 placeholders
>>>
```

While the above examples use `print()` to show how the formatting works, you would of course use `logger.debug()` or similar to actually log using this approach.

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That's because the `_` notation is just syntax sugar for a constructor call to one of the `XXXMessage` classes.

If you prefer, you can use a `LoggerAdapter` to achieve a similar effect to the above, as in the following example:

```
import logging
```

```

class Message:
    def __init__(self, fmt, args):
        self.fmt = fmt
        self.args = args

    def __str__(self):
        return self.fmt.format(*self.args)

class StyleAdapter(logging.LoggerAdapter):
    def __init__(self, logger, extra=None):
        super().__init__(logger, extra or {})

    def log(self, level, msg, /, *args, **kwargs):
        if self.isEnabledFor(level):
            msg, kwargs = self.process(msg, kwargs)
            self.logger._log(level, Message(msg, args),

logger = StyleAdapter(logging.getLogger(__name__))

def main():
    logger.debug('Hello, {}, 'world!')

if __name__ == '__main__':
    logging.basicConfig(level=logging.DEBUG)
    main()

```

The above script should log the message `Hello, world!` when run with Python 3.2 or later.

## Customizing LogRecord

Every logging event is represented by a [LogRecord](#) instance. When an event is logged and not filtered out by a logger's level, a [LogRecord](#) is created, populated with information about the event and then passed to the handlers for that logger (and its ancestors, up to and including the logger where further propagation up the hierarchy is disabled). Before Python 3.2, there were only two

places where this creation was done:

- `Logger.makeRecord()`, which is called in the normal process of logging an event. This invoked `LogRecord` directly to create an instance.
- `makeLogRecord()`, which is called with a dictionary containing attributes to be added to the `LogRecord`. This is typically invoked when a suitable dictionary has been received over the network (e.g. in pickle form via a `SocketHandler`, or in JSON form via an `HTTPHandler`).

This has usually meant that if you need to do anything special with a `LogRecord`, you've had to do one of the following.

- Create your own `Logger` subclass, which overrides `Logger.makeRecord()`, and set it using `setLoggerClass()` before any loggers that you care about are instantiated.
- Add a `Filter` to a logger or handler, which does the necessary special manipulation you need when its `filter()` method is called.

The first approach would be a little unwieldy in the scenario where (say) several different libraries wanted to do different things. Each would attempt to set its own `Logger` subclass, and the one which did this last would win.

The second approach works reasonably well for many cases, but does not allow you to e.g. use a specialized subclass of `LogRecord`. Library developers can set a suitable filter on their loggers, but they would have to remember to do this every time they introduced a new logger (which they would do simply by adding new packages or modules and doing

```
logger = logging.getLogger(__name__)
```

at module level). It's probably one too many things to think about. Developers could also add the filter to a `NullHandler` attached to their top-level logger, but this would not be invoked if an application developer attached a handler to a lower-level library logger — so output from that handler would not reflect the

intentions of the library developer.

In Python 3.2 and later, **LogRecord** creation is done through a factory, which you can specify. The factory is just a callable you can set with **setLogRecordFactory()**, and interrogate with **getLogRecordFactory()**. The factory is invoked with the same signature as the **LogRecord** constructor, as **LogRecord** is the default setting for the factory.

This approach allows a custom factory to control all aspects of **LogRecord** creation. For example, you could return a subclass, or just add some additional attributes to the record once created, using a pattern similar to this:

```
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
    record = old_factory(*args, **kwargs)
    record.custom_attribute = 0xdeadbeef
    return record

logging.setLogRecordFactory(record_factory)
```

This pattern allows different libraries to chain factories together, and as long as they don't overwrite each other's attributes or unintentionally overwrite the attributes provided as standard, there should be no surprises. However, it should be borne in mind that each link in the chain adds run-time overhead to all logging operations, and the technique should only be used when the use of a **Filter** does not provide the desired result.

## Subclassing QueueHandler - a ZeroMQ example

You can use a **QueueHandler** subclass to send messages to other kinds of queues, for example a ZeroMQ 'publish' socket. In the example below, the socket is created separately and passed to the handler (as its 'queue'):

```

import zmq    # using pyzmq, the Python binding for ZeroMQ
import json   # for serializing records portably

ctx = zmq.Context()
sock = zmq.Socket(ctx, zmq.PUB)    # or zmq.PUSH, or other
sock.bind('tcp://*:5556')         # or wherever

class ZeroMQSocketHandler(QueueHandler):
    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

handler = ZeroMQSocketHandler(sock)

```

Of course there are other ways of organizing this, for example passing in the data needed by the handler to create the socket:

```

class ZeroMQSocketHandler(QueueHandler):
    def __init__(self, uri, socktype=zmq.PUB, ctx=None):
        self.ctx = ctx or zmq.Context()
        socket = zmq.Socket(self.ctx, socktype)
        socket.bind(uri)
        super().__init__(socket)

    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

    def close(self):
        self.queue.close()

```

## Subclassing QueueListener - a ZeroMQ example

You can also subclass [QueueListener](#) to get messages from other kinds of queues, for example a ZeroMQ ‘subscribe’ socket. Here’s an example:

```

class ZeroMQSocketListener(QueueListener):

```

```
def __init__(self, uri, /, *handlers, **kwargs):
    self.ctx = kwargs.get('ctx') or zmq.Context()
    socket = zmq.Socket(self.ctx, zmq.SUB)
    socket.setsockopt_string(zmq.SUBSCRIBE, '') # s
    socket.connect(uri)
    super().__init__(socket, *handlers, **kwargs)

def dequeue(self):
    msg = self.queue.recv_json()
    return logging.makeLogRecord(msg)
```

## An example dictionary-based configuration

Below is an example of a logging configuration dictionary - it's taken from the [documentation on the Django project](https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging) [https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging]. This dictionary is passed to [dictConfig\(\)](#) to put the configuration into effect:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': True,
```

```
'formatters': {
    'verbose': {
        'format': '%(levelname)s %(asctime)s %(module)s',
    },
    'simple': {
        'format': '%(levelname)s %(message)s'
    },
},
'filters': {
    'special': {
        '()': 'project.logging.SpecialFilter',
        'foo': 'bar',
    }
},
'handlers': {
    'null': {
        'level': 'DEBUG',
        'class': 'django.utils.log.NullHandler',
    },
    'console': {
        'level': 'DEBUG',
        'class': 'logging.StreamHandler',
        'formatter': 'simple'
    },
    'mail_admins': {
        'level': 'ERROR',
        'class': 'django.utils.log.AdminEmailHandler',
        'filters': ['special']
    }
},
'loggers': {
    'django': {
        'handlers': ['null'],
        'propagate': True,
        'level': 'INFO',
    },
    'django.request': {
        'handlers': ['mail_admins'],
```

```

        'level': 'ERROR',
        'propagate': False,
    },
    'myproject.custom': {
        'handlers': ['console', 'mail_admins'],
        'level': 'INFO',
        'filters': ['special']
    }
}

```

For more information about this configuration, you can see the [relevant section](https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging) [https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging] of the Django documentation.

## Using a rotator and namer to customize log rotation processing

An example of how you can define a namer and rotator is given in the following runnable script, which shows gzip compression of the log file:

```

import gzip
import logging
import logging.handlers
import os
import shutil

def namer(name):
    return name + ".gz"

def rotator(source, dest):
    with open(source, 'rb') as f_in:
        with gzip.open(dest, 'wb') as f_out:
            shutil.copyfileobj(f_in, f_out)
    os.remove(source)

```

```
rh = logging.handlers.RotatingFileHandler('rotated.log',
rh.rotator = rotator
rh.namer = namer

root = logging.getLogger()
root.setLevel(logging.INFO)
root.addHandler(rh)
f = logging.Formatter('%(asctime)s %(message)s')
rh.setFormatter(f)
for i in range(1000):
    root.info(f'Message no. {i + 1}')
```

After running this, you will see six new files, five of which are compressed:

```
$ ls rotated.log*
rotated.log          rotated.log.2.gz    rotated.log.4.gz
rotated.log.1.gz    rotated.log.3.gz    rotated.log.5.gz
$ zcat rotated.log.1.gz
2023-01-20 02:28:17,767 Message no. 996
2023-01-20 02:28:17,767 Message no. 997
2023-01-20 02:28:17,767 Message no. 998
```

## A more elaborate multiprocessing example

The following working example shows how logging can be used with multiprocessing using configuration files. The configurations are fairly simple, but serve to illustrate how more complex ones could be implemented in a real multiprocessing scenario.

In the example, the main process spawns a listener process and some worker processes. Each of the main process, the listener and the workers have three separate configurations (the workers all share the same configuration). We can see logging in the main process, how the workers log to a QueueHandler and how the listener implements a QueueListener and a more complex logging configuration, and arranges to dispatch events received via the queue to the handlers specified in the configuration. Note that these

configurations are purely illustrative, but you should be able to adapt this example to your own scenario.

Here's the script - the docstrings and the comments hopefully explain how it works:

```
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue, Event, current_process
import os
import random
import time

class MyHandler:
    """
    A simple handler for logging events. It runs in the background
    and dispatches events to loggers based on the name in the config.
    The loggers then get dispatched, by the logging system, to the
    handlers configured for those loggers.
    """

    def handle(self, record):
        if record.name == "root":
            logger = logging.getLogger()
        else:
            logger = logging.getLogger(record.name)

        if logger.isEnabledFor(record.levelno):
            # The process name is transformed just to show it's in a
            # subprocess doing the logging to files and console
            record.processName = '%s (for %s)' % (current_process().name, record.name)
            logger.handle(record)

def listener_process(q, stop_event, config):
    """
    This could be done in the main process, but is just a
    process for illustrative purposes.
    """
```

This initialises logging according to the specified  
starts the listener and waits for the main process t  
via the event. The listener is then stopped, and the  
"""

```
logging.config.dictConfig(config)
listener = logging.handlers.QueueListener(q, MyHandler)
listener.start()
if os.name == 'posix':
    # On POSIX, the setup logger will have been confi
    # parent process, but should have been disabled
    # dictConfig call.
    # On Windows, since fork isn't used, the setup l
    # exist in the child, so it would be created and
    # would appear - hence the "if posix" clause.
    logger = logging.getLogger('setup')
    logger.critical('Should not appear, because of o
stop_event.wait()
listener.stop()
```

```
def worker_process(config):
    """
    A number of these are spawned for the purpose of ill
    practice, they could be a heterogeneous bunch of pro
    ones which are identical to each other.
```

This initialises logging according to the specified  
and logs a hundred messages with random levels to ra  
loggers.

A small sleep is added to allow other processes a ch  
is not strictly needed, but it mixes the output from  
processes a bit more than if it's left out.

```
"""
logging.config.dictConfig(config)
levels = [logging.DEBUG, logging.INFO, logging.WARNI
          logging.CRITICAL]
loggers = ['foo', 'foo.bar', 'foo.bar.baz',
           'spam', 'spam.ham', 'spam.ham.eggs']
```

```

if os.name == 'posix':
    # On POSIX, the setup logger will have been conf
    # parent process, but should have been disabled
    # dictConfig call.
    # On Windows, since fork isn't used, the setup l
    # exist in the child, so it would be created and
    # would appear - hence the "if posix" clause.
    logger = logging.getLogger('setup')
    logger.critical('Should not appear, because of o
for i in range(100):
    lvl = random.choice(levels)
    logger = logging.getLogger(random.choice(loggers
    logger.log(lvl, 'Message no. %d', i)
    time.sleep(0.01)

```

```

def main():
    q = Queue()
    # The main process gets a simple configuration which
    config_initial = {
        'version': 1,
        'handlers': {
            'console': {
                'class': 'logging.StreamHandler',
                'level': 'INFO'
            }
        },
        'root': {
            'handlers': ['console'],
            'level': 'DEBUG'
        }
    }
    # The worker process configuration is just a QueueHa
    # root logger, which allows all messages to be sent
    # We disable existing loggers to disable the "setup"
    # parent process. This is needed on POSIX because th
    # be there in the child following a fork().
    config_worker = {
        'version': 1,

```

```

'disable_existing_loggers': True,
'handlers': {

    for wp in workers:
        wp.join()
    # Workers all done, listening can now stop.
    # Logging in the parent still works normally.
    logger.info('Telling listener to stop ...')
    stop_event.set()
    lp.join()
    logger.info('All done.')

if __name__ == '__main__':
    main()

```

## Inserting a BOM into messages sent to a SysLogHandler

**RFC 5424** [<https://datatracker.ietf.org/doc/html/rfc5424.html>] requires that a Unicode message be sent to a syslog daemon as a set of bytes which have the following structure: an optional pure-ASCII component, followed by a UTF-8 Byte Order Mark (BOM), followed by Unicode encoded using UTF-8. (See the [relevant section of the specification](https://datatracker.ietf.org/doc/html/rfc5424.html#section-6) [<https://datatracker.ietf.org/doc/html/rfc5424.html#section-6>].)

In Python 3.1, code was added to **SysLogHandler** to insert a BOM into the message, but unfortunately, it was implemented incorrectly, with the BOM appearing at the beginning of the message and hence not allowing any pure-ASCII component to appear before it.

As this behaviour is broken, the incorrect BOM insertion code is being removed from Python 3.2.4 and later. However, it is not being replaced, and if you want to produce [RFC 5424](https://datatracker.ietf.org/doc/html/rfc5424.html) [https://datatracker.ietf.org/doc/html/rfc5424.html]-compliant messages which include a BOM, an optional pure-ASCII sequence before it and arbitrary Unicode after it, encoded using UTF-8, then you need to do the following:

1. Attach a **Formatter** instance to your **SysLogHandler** instance, with a format string such as:

```
'ASCII section\ufeffUnicode section'
```

The Unicode code point U+FEFF, when encoded using UTF-8, will be encoded as a UTF-8 BOM – the byte-string `b'\xef\xbb\xbf'`.

2. Replace the ASCII section with whatever placeholders you like, but make sure that the data that appears in there after substitution is always ASCII (that way, it will remain unchanged after UTF-8 encoding).
3. Replace the Unicode section with whatever placeholders you like; if the data which appears there after substitution contains characters outside the ASCII range, that's fine – it will be encoded using UTF-8.

The formatted message *will* be encoded using UTF-8 encoding by `SysLogHandler`. If you follow the above rules, you should be able to produce [RFC 5424](https://datatracker.ietf.org/doc/html/rfc5424.html) [https://datatracker.ietf.org/doc/html/rfc5424.html]-compliant messages. If you don't, logging may not complain, but your messages will not be RFC 5424-compliant, and your syslog daemon may complain.

## Implementing structured logging

Although most logging messages are intended for reading by humans, and thus not readily machine-parseable, there might be circumstances where you want to output messages in a structured format which is capable of being parsed by a program (without

needing complex regular expressions to parse the log message). This is straightforward to achieve using the logging package. There are a number of ways in which this could be achieved, but the following is a simple approach which uses JSON to serialise the event in a machine-parseable manner:

```
import json
import logging

class StructuredMessage:
    def __init__(self, message, /, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        return '%s >>> %s' % (self.message, json.dumps(s

_ = StructuredMessage    # optional, to improve readability

logging.basicConfig(level=logging.INFO, format='%(message)s')
logging.info(_('message 1', foo='bar', bar='baz', num=123))
```

If the above script is run, it prints:

```
message 1 >>> {"fnum": 123.456, "num": 123, "bar": "baz", "foo": "bar"}
```

Note that the order of items might be different according to the version of Python used.

If you need more specialised processing, you can use a custom JSON encoder, as in the following complete example:

```
import json
import logging

class Encoder(json.JSONEncoder):
    def default(self, o):
        if isinstance(o, set):
            return tuple(o)
```

```

        elif isinstance(o, str):
            return o.encode('unicode_escape').decode('as
        return super().default(o)

class StructuredMessage:
    def __init__(self, message, /, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        s = Encoder().encode(self.kwargs)
        return '%s >>> %s' % (self.message, s)

_ = StructuredMessage    # optional, to improve readability

def main():
    logging.basicConfig(level=logging.INFO, format='%(me
    logging.info(_('message 1', set_value={1, 2, 3}, sno

if __name__ == '__main__':
    main()

```

When the above script is run, it prints:

```
message 1 >>> {"snowman": "\u2603", "set_value": [1, 2,
```

Note that the order of items might be different according to the version of Python used.

## Customizing handlers with `dictConfig()`

There are times when you want to customize logging handlers in particular ways, and if you use `dictConfig()` you may be able to do this without subclassing. As an example, consider that you may want to set the ownership of a log file. On POSIX, this is easily done using `shutil.chown()`, but the file handlers in the stdlib don't offer built-in support. You can customize handler creation using a

plain function such as:

```
def owned_file_handler(filename, mode='a', encoding=None):
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
            shutil.chown(filename, *owner)
    return logging.FileHandler(filename, mode, encoding)
```

You can then specify, in a logging configuration passed to `dictConfig()`, that a logging handler be created by calling this function:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'default': {
            'format': '%(asctime)s %(levelname)s %(name)s',
        },
    },
    'handlers': {
        'file': {
            # The values below are popped from this dict
            # used to create the handler, set the handler
            # its formatter.
            '()': owned_file_handler,
            'level': 'DEBUG',
            'formatter': 'default',
            # The values below are passed to the handler
            # as keyword arguments.
            'owner': ['pulse', 'pulse'],
            'filename': 'chowntest.log',
            'mode': 'w',
            'encoding': 'utf-8',
        },
    },
    'root': {
        'handlers': ['file'],
    },
}
```

```

        'level': 'DEBUG',
    },
}

```

In this example I am setting the ownership using the `pulse` user and group, just for the purposes of illustration. Putting it together into a working script, `chowntest.py`:

```

import logging, logging.config, os, shutil

def owned_file_handler(filename, mode='a', encoding=None):
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
            shutil.chown(filename, *owner)
    return logging.FileHandler(filename, mode, encoding)

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'default': {
            'format': '%(asctime)s %(levelname)s %(name)s',
        },
    },
    'handlers': {
        'file': {
            # The values below are popped from this dict
            # used to create the handler, set the handler
            # its formatter.
            '()': owned_file_handler,
            'level': 'DEBUG',
            'formatter': 'default',
            # The values below are passed to the handler
            # as keyword arguments.
            'owner': ['pulse', 'pulse'],
            'filename': 'chowntest.log',
            'mode': 'w',
            'encoding': 'utf-8',
        },
    },
}

```

```

        },
    },
    'root': {
        'handlers': ['file'],
        'level': 'DEBUG',
    },
}

```

```

logging.config.dictConfig(LOGGING)
logger = logging.getLogger('mylogger')
logger.debug('A debug message')

```

To run this, you will probably need to run as root:

```

$ sudo python3.3 chowntest.py
$ cat chowntest.log
2013-11-05 09:34:51,128 DEBUG mylogger A debug message
$ ls -l chowntest.log
-rw-r--r-- 1 pulse pulse 55 2013-11-05 09:34 chowntest.log

```

Note that this example uses Python 3.3 because that's where `shutil.chown()` makes an appearance. This approach should work with any Python version that supports `dictConfig()` - namely, Python 2.7, 3.2 or later. With pre-3.3 versions, you would need to implement the actual ownership change using e.g. `os.chown()`.

In practice, the handler-creating function may be in a utility module somewhere in your project. Instead of the line in the configuration:

```
'()': owned_file_handler,
```

you could use e.g.:

```
'()': 'ext://project.util.owned_file_handler',
```

where `project.util` can be replaced with the actual name of the package where the function resides. In the above working script, using `'ext://__main__.owned_file_handler'` should work. Here, the actual callable is resolved by `dictConfig()` from the `ext://` specification.

This example hopefully also points the way to how you could implement other types of file change - e.g. setting specific POSIX permission bits - in the same way, using `os.chmod()`.

Of course, the approach could also be extended to types of handler other than a `FileHandler` - for example, one of the rotating file handlers, or a different type of handler altogether.

## Using particular formatting styles throughout your application

In Python 3.2, the `Formatter` gained a `style` keyword parameter which, while defaulting to `%` for backward compatibility, allowed the specification of `{` or `$` to support the formatting approaches supported by `str.format()` and `string.Template`. Note that this governs the formatting of logging messages for final output to logs, and is completely orthogonal to how an individual logging message is constructed.

Logging calls (`debug()`, `info()` etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged, or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using `str.format()` or `string.Template` syntax, because internally the logging package uses `%`-formatting to merge the format string and the variable arguments. There would be no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using `%`-format strings.

There have been suggestions to associate format styles with specific loggers, but that approach also runs into backward compatibility problems because any existing code could be using a given logger name and using `%`-formatting.

For logging to work interoperably between any third-party libraries and your code, decisions about formatting need to be made at the

level of the individual logging call. This opens up a couple of ways in which alternative formatting styles can be accommodated.

## Using LogRecord factories

In Python 3.2, along with the `Formatter` changes mentioned above, the logging package gained the ability to allow users to set their own `LogRecord` subclasses, using the `setLogRecordFactory()` function. You can use this to set your own subclass of `LogRecord`, which does the Right Thing by overriding the `getMessage()` method. The base class implementation of this method is where the `msg % args` formatting happens, and where you can substitute your alternate formatting; however, you should be careful to support all formatting styles and allow %-formatting as the default, to ensure interoperability with other code. Care should also be taken to call `str(self.msg)`, just as the base implementation does.

Refer to the reference documentation on `setLogRecordFactory()` and `LogRecord` for more information.

## Using custom message objects

There is another, perhaps simpler way that you can use {}- and \$-formatting to construct your individual log messages. You may recall (from [Using arbitrary objects as messages](#)) that when logging you can use an arbitrary object as a message format string, and that the logging package will call `str()` on that object to get the actual format string. Consider the following two classes:

```
class BraceMessage:
    def __init__(self, fmt, /, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs)
```

```

class DollarMessage:
    def __init__(self, fmt, /, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwargs)

```

Either of these can be used in place of a format string, to allow {}- or \$-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “\$message”. If you find it a little unwieldy to use the class names whenever you want to log something, you can make it more palatable if you use an alias such as `M` or `_` for the message (or perhaps `__`, if you are using `_` for localization).

Examples of this approach are given below. Firstly, formatting with `str.format()`:

```

>>> __ = BraceMessage
>>> print(__('Message with {0} {1}', 2, 'placeholders'))
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f},
Message with coordinates: (0.50, 0.50)

```

Secondly, formatting with `string.Template`:

```

>>> __ = DollarMessage
>>> print(__('Message with $num $what', num=2, what='pla
Message with 2 placeholders
>>>

```

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when

you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That's because the `_` notation is just syntax sugar for a constructor call to one of the `XXXMessage` classes shown above.

## Configuring filters with `dictConfig()`

You *can* configure filters using `dictConfig()`, though it might not be obvious at first glance how to do it (hence this recipe). Since `Filter` is the only filter class included in the standard library, and it is unlikely to cater to many requirements (it's only there as a base class), you will typically need to define your own `Filter` subclass with an overridden `filter()` method. To do this, specify the `filter` key in the configuration dictionary for the filter, specifying a callable which will be used to create the filter (a class is the most obvious, but you can provide any callable which returns a `Filter` instance). Here is a complete example:

```
import logging
import logging.config
import sys

class MyFilter(logging.Filter):
    def __init__(self, param=None):
        self.param = param

    def filter(self, record):
        if self.param is None:
            allow = True
        else:
            allow = self.param not in record.msg
        if allow:
            record.msg = 'changed: ' + record.msg
        return allow

LOGGING = {
```

```

'version': 1,
'filters': {
    'myfilter': {
        '()': MyFilter,
        'param': 'noshow',
    }
},
'handlers': {
    'console': {
        'class': 'logging.StreamHandler',
        'filters': ['myfilter']
    }
},
'root': {
    'level': 'DEBUG',
    'handlers': ['console']
},
}

if __name__ == '__main__':
    logging.config.dictConfig(LOGGING)
    logging.debug('hello')
    logging.debug('hello - noshow')

```

This example shows how you can pass configuration data to the callable which constructs the instance, in the form of keyword parameters. When run, the above script will print:

```
changed: hello
```

which shows that the filter is working as configured.

A couple of extra points to note:

- If you can't refer to the callable directly in the configuration (e.g. if it lives in a different module, and you can't import it directly where the configuration dictionary is), you can use the form `ext://...` as described in [Access to external objects](#). For example, you could have used the text `'ext://__main__.MyFilter'` instead of `MyFilter` in the above

example.

- As well as for filters, this technique can also be used to configure custom handlers and formatters. See [User-defined objects](#) for more information on how logging supports using user-defined objects in its configuration, and see the other cookbook recipe [Customizing handlers with dictConfig\(\)](#) above.

## Customized exception formatting

There might be times when you want to do customized exception formatting - for argument's sake, let's say you want exactly one line per logged event, even when exception information is present. You can do this with a custom formatter class, as shown in the following example:

```
import logging
```

```
class OneLineExceptionFormatter(logging.Formatter):
```

```
    def formatException(self, exc_info):
```

```
        """
```

```
        Format an exception so that it prints on a single
```

```
        """
```

```
        result = super().formatException(exc_info)
```

```
        return repr(result) # or format into one line h
```

```
    def format(self, record):
```

```
        s = super().format(record)
```

```
        if record.exc_text:
```

```
            s = s.replace('\n', ' ') + '|'
```

```
        return s
```

```
def configure_logging():
```

```
    fh = logging.FileHandler('output.txt', 'w')
```

```
    f = OneLineExceptionFormatter('%(asctime)s|%(levelname
```

```
                                '%d/%m/%Y %H:%M:%S')
```

```
    fh.setFormatter(f)
```

```
    root = logging.getLogger()
```

```
    root.setLevel(logging.DEBUG)
```

```

root.addHandler(fh)

def main():
    configure_logging()
    logging.info('Sample message')
    try:
        x = 1 / 0
    except ZeroDivisionError as e:
        logging.exception('ZeroDivisionError: %s', e)

if __name__ == '__main__':
    main()

```

When run, this produces a file with exactly two lines:

```

28/01/2015 07:21:23|INFO|Sample message|
28/01/2015 07:21:23|ERROR|ZeroDivisionError: integer div

```

While the above treatment is simplistic, it points the way to how exception information can be formatted to your liking. The [traceback](#) module may be helpful for more specialized needs.

## Speaking logging messages

There might be situations when it is desirable to have logging messages rendered in an audible rather than a visible format. This is easy to do if you have text-to-speech (TTS) functionality available in your system, even if it doesn't have a Python binding. Most TTS systems have a command line program you can run, and this can be invoked from a handler using [subprocess](#). It's assumed here that TTS command line programs won't expect to interact with users or take a long time to complete, and that the frequency of logged messages will be not so high as to swamp the user with messages, and that it's acceptable to have the messages spoken one at a time rather than concurrently. The example implementation below waits for one message to be spoken before the next is processed, and this might cause other handlers to be kept waiting. Here is a short example showing the approach, which assumes that the `espeak` TTS package is available:

```

import logging
import subprocess
import sys

class TTSHandler(logging.Handler):
    def emit(self, record):
        msg = self.format(record)
        # Speak slowly in a female English voice
        cmd = ['espeak', '-s150', '-ven+f3', msg]
        p = subprocess.Popen(cmd, stdout=subprocess.PIPE,
                             stderr=subprocess.STDOUT)
        # wait for the program to finish
        p.communicate()

def configure_logging():
    h = TTSHandler()
    root = logging.getLogger()
    root.addHandler(h)
    # the default formatter just returns the message
    root.setLevel(logging.DEBUG)

def main():
    logging.info('Hello')
    logging.debug('Goodbye')

if __name__ == '__main__':
    configure_logging()
    sys.exit(main())

```

When run, this script should say “Hello” and then “Goodbye” in a female voice.

The above approach can, of course, be adapted to other TTS systems and even other systems altogether which can process messages via external programs run from a command line.

## Buffering logging messages and outputting them conditionally

There might be situations where you want to log messages in a temporary area and only output them if a certain condition occurs. For example, you may want to start logging debug events in a function, and if the function completes without errors, you don't want to clutter the log with the collected debug information, but if there is an error, you want all the debug information to be output as well as the error.

Here is an example which shows how you could do this using a decorator for your functions where you want logging to behave this way. It makes use of the `logging.handlers.MemoryHandler`, which allows buffering of logged events until some condition occurs, at which point the buffered events are flushed - passed to another handler (the target handler) for processing. By default, the `MemoryHandler` flushed when its buffer gets filled up or an event whose level is greater than or equal to a specified threshold is seen. You can use this recipe with a more specialised subclass of `MemoryHandler` if you want custom flushing behavior.

The example script has a simple function, `foo`, which just cycles through all the logging levels, writing to `sys.stderr` to say what level it's about to log at, and then actually logging a message at that level. You can pass a parameter to `foo` which, if true, will log at `ERROR` and `CRITICAL` levels - otherwise, it only logs at `DEBUG`, `INFO` and `WARNING` levels.

The script just arranges to decorate `foo` with a decorator which will do the conditional logging that's required. The decorator takes a logger as a parameter and attaches a memory handler for the duration of the call to the decorated function. The decorator can be additionally parameterised using a target handler, a level at which flushing should occur, and a capacity for the buffer (number of records buffered). These default to a `StreamHandler` which writes to `sys.stderr`, `logging.ERROR` and `100` respectively.

Here's the script:

```
import logging
from logging.handlers import MemoryHandler
import sys
```

```

logger = logging.getLogger(__name__)
logger.addHandler(logging.NullHandler())

def log_if_errors(logger, target_handler=None, flush_level=logging.ERROR):
    if target_handler is None:
        target_handler = logging.StreamHandler()
    if flush_level is None:
        flush_level = logging.ERROR
    if capacity is None:
        capacity = 100
    handler = MemoryHandler(capacity, flushLevel=flush_level)

    def decorator(fn):
        def wrapper(*args, **kwargs):
            logger.addHandler(handler)
            try:
                return fn(*args, **kwargs)
            except Exception:
                logger.exception('call failed')
                raise
            finally:
                super(MemoryHandler, handler).flush()
                logger.removeHandler(handler)
        return wrapper

    return decorator

def write_line(s):
    sys.stderr.write('%s\n' % s)

def foo(fail=False):
    write_line('about to log at DEBUG ...')
    logger.debug('Actually logged at DEBUG')
    write_line('about to log at INFO ...')
    logger.info('Actually logged at INFO')
    write_line('about to log at WARNING ...')
    logger.warning('Actually logged at WARNING')
    if fail:

```

```
        write_line('about to log at ERROR ...')
        logger.error('Actually logged at ERROR')
        write_line('about to log at CRITICAL ...')
        logger.critical('Actually logged at CRITICAL')
    return fail
```

```
decorated_foo = log_if_errors(logger)(foo)
```

```
if __name__ == '__main__':
    logger.setLevel(logging.DEBUG)
    write_line('Calling undecorated foo with False')
    assert not foo(False)
    write_line('Calling undecorated foo with True')
    assert foo(True)
    write_line('Calling decorated foo with False')
    assert not decorated_foo(False)
    write_line('Calling decorated foo with True')
    assert decorated_foo(True)
```

**When this script is run, the following output should be observed:**

```
Calling undecorated foo with False
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
Calling undecorated foo with True
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
about to log at ERROR ...
about to log at CRITICAL ...
Calling decorated foo with False
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
Calling decorated foo with True
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
```

```
about to log at ERROR ...
Actually logged at DEBUG
Actually logged at INFO
Actually logged at WARNING
Actually logged at ERROR
about to log at CRITICAL ...
Actually logged at CRITICAL
```

As you can see, actual logging output only occurs when an event is logged whose severity is ERROR or greater, but in that case, any previous events at lower severities are also logged.

You can of course use the conventional means of decoration:

```
@log_if_errors(logger)
def foo(fail=False):
    ...
```

## **Sending logging messages to email, with buffering**

To illustrate how you can send log messages via email, so that a set number of messages are sent per email, you can subclass [BufferingHandler](#). In the following example, which you can adapt to suit your specific needs, a simple test harness is provided which allows you to run the script with command line arguments specifying what you typically need to send things via SMTP. (Run the downloaded script with the `-h` argument to see the required and optional arguments.)

```
import logging
import logging.handlers
import smtplib

class BufferingSMTPHandler(logging.handlers.BufferingHandler):
    def __init__(self, mailhost, port, username, password,
                  subject, capacity):
        logging.handlers.BufferingHandler.__init__(self, capacity)
        self.mailhost = mailhost
```

```

        self.mailport = port
        self.username = username
        self.password = password
        self.fromaddr = fromaddr
        if isinstance(toaddrs, str):
            toaddrs = [toaddrs]
        self.toaddrs = toaddrs
        self.subject = subject
        self.setFormatter(logging.Formatter("%(asctime)s

def flush(self):
    if len(self.buffer) > 0:
        try:
            smtp = smtplib.SMTP(self.mailhost, self.
            smtp.starttls()
            smtp.login(self.username, self.password)
            msg = "From: %s\r\nTo: %s\r\nSubject: %s\r\n"
            for record in self.buffer:
                s = self.format(record)
                msg = msg + s + "\r\n"
            smtp.sendmail(self.fromaddr, self.toaddrs, msg)
            smtp.quit()
        except Exception:
            if logging.raiseExceptions:
                raise
        self.buffer = []

if __name__ == '__main__':
    import argparse

    ap = argparse.ArgumentParser()
    aa = ap.add_argument
    aa('host', metavar='HOST', help='SMTP server')
    aa('--port', '-p', type=int, default=587, help='SMTP port')
    aa('user', metavar='USER', help='SMTP username')
    aa('password', metavar='PASSWORD', help='SMTP password')
    aa('to', metavar='TO', help='Addressee for emails')
    aa('sender', metavar='SENDER', help='Sender email address')

```

```

aa('--subject', '-s',
    default='Test Logging email from Python logging m
    help='Subject of email')
options = ap.parse_args()
logger = logging.getLogger()
logger.setLevel(logging.DEBUG)
h = BufferingSMTPHandler(options.host, options.port,
                        options.password, options.s
                        options.to, options.subject

logger.addHandler(h)
for i in range(102):
    logger.info("Info index = %d", i)
h.flush()
h.close()

```

If you run this script and your SMTP server is correctly set up, you should find that it sends eleven emails to the addressee you specify. The first ten emails will each have ten log messages, and the eleventh will have two messages. That makes up 102 messages as specified in the script.

## Formatting times using UTC (GMT) via configuration

Sometimes you want to format times using UTC, which can be done using a class such as `UTCFormatter`, shown below:

```

import logging
import time

class UTCFormatter(logging.Formatter):
    converter = time.gmtime

```

and you can then use the `UTCFormatter` in your code instead of **`Formatter`**. If you want to do that via configuration, you can use the **`dictConfig()`** API with an approach illustrated by the following complete example:

```

import logging

```

```

import logging.config
import time

class UTCFormatter(logging.Formatter):
    converter = time.gmtime

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'utc': {
            '()': UTCFormatter,
            'format': '%(asctime)s %(message)s',
        },
        'local': {
            'format': '%(asctime)s %(message)s',
        }
    },
    'handlers': {
        'console1': {
            'class': 'logging.StreamHandler',
            'formatter': 'utc',
        },
        'console2': {
            'class': 'logging.StreamHandler',
            'formatter': 'local',
        },
    },
    'root': {
        'handlers': ['console1', 'console2'],
    }
}

if __name__ == '__main__':
    logging.config.dictConfig(LOGGING)
    logging.warning('The local time is %s', time.asctime)

```

When this script is run, it should print something like:

```
2015-10-17 12:53:29,501 The local time is Sat Oct 17 13:
```

```
2015-10-17 13:53:29,501 The local time is Sat Oct 17 13:
```

showing how the time is formatted both as local time and UTC, one for each handler.

## Using a context manager for selective logging

There are times when it would be useful to temporarily change the logging configuration and revert it back after doing something. For this, a context manager is the most obvious way of saving and restoring the logging context. Here is a simple example of such a context manager, which allows you to optionally change the logging level and add a logging handler purely in the scope of the context manager:

```
import logging
import sys

class LoggingContext:
    def __init__(self, logger, level=None, handler=None,
                 self.logger = logger
                 self.level = level
                 self.handler = handler
                 self.close = close

    def __enter__(self):
        if self.level is not None:
            self.old_level = self.logger.level
            self.logger.setLevel(self.level)
        if self.handler:
            self.logger.addHandler(self.handler)

    def __exit__(self, et, ev, tb):
        if self.level is not None:
            self.logger.setLevel(self.old_level)
        if self.handler:
```

```

        self.logger.removeHandler(self.handler)
    if self.handler and self.close:
        self.handler.close()
    # implicit return of None => don't swallow exceptions

```

If you specify a level value, the logger's level is set to that value in the scope of the with block covered by the context manager. If you specify a handler, it is added to the logger on entry to the block and removed on exit from the block. You can also ask the manager to close the handler for you on block exit - you could do this if you don't need the handler any more.

To illustrate how it works, we can add the following block of code to the above:

```

if __name__ == '__main__':
    logger = logging.getLogger('foo')
    logger.addHandler(logging.StreamHandler())
    logger.setLevel(logging.INFO)
    logger.info('1. This should appear just once on stderr')
    logger.debug('2. This should not appear.')
    with LoggingContext(logger, level=logging.DEBUG):
        logger.debug('3. This should appear once on stderr')
    logger.debug('4. This should not appear.')
    h = logging.StreamHandler(sys.stdout)
    with LoggingContext(logger, level=logging.DEBUG, handler=h):
        logger.debug('5. This should appear twice - once on stderr and once on stdout')
    logger.info('6. This should appear just once on stderr')
    logger.debug('7. This should not appear.')

```

We initially set the logger's level to `INFO`, so message #1 appears and message #2 doesn't. We then change the level to `DEBUG` temporarily in the following `with` block, and so message #3 appears. After the block exits, the logger's level is restored to `INFO` and so message #4 doesn't appear. In the next `with` block, we set the level to `DEBUG` again but also add a handler writing to `sys.stdout`. Thus, message #5 appears twice on the console (once via `stderr` and once via `stdout`). After the `with` statement's completion, the status is as it was before so message #6 appears (like message #1) whereas message #7 doesn't (just like

message #2).

If we run the resulting script, the result is as follows:

```
$ python logctx.py
1. This should appear just once on stderr.
3. This should appear once on stderr.
5. This should appear twice - once on stderr and once on
5. This should appear twice - once on stderr and once on
6. This should appear just once on stderr.
```

If we run it again, but pipe `stderr` to `/dev/null`, we see the following, which is the only message written to `stdout`:

```
$ python logctx.py 2>/dev/null
5. This should appear twice - once on stderr and once on
```

Once again, but piping `stdout` to `/dev/null`, we get:

```
$ python logctx.py >/dev/null
1. This should appear just once on stderr.
3. This should appear once on stderr.
5. This should appear twice - once on stderr and once on
6. This should appear just once on stderr.
```

In this case, the message #5 printed to `stdout` doesn't appear, as expected.

Of course, the approach described here can be generalised, for example to attach logging filters temporarily. Note that the above code works in Python 2 as well as Python 3.

## A CLI application starter template

Here's an example which shows how you can:

- Use a logging level based on command-line arguments
- Dispatch to multiple subcommands in separate files, all logging at the same level in a consistent way
- Make use of simple, minimal configuration

Suppose we have a command-line application whose job is to stop, start or restart some services. This could be organised for the purposes of illustration as a file `app.py` that is the main script for the application, with individual commands implemented in `start.py`, `stop.py` and `restart.py`. Suppose further that we want to control the verbosity of the application via a command-line argument, defaulting to `logging.INFO`. Here's one way that `app.py` could be written:

```
import argparse
import importlib
import logging
import os
import sys

def main(args=None):
    scriptname = os.path.basename(__file__)
    parser = argparse.ArgumentParser(scriptname)
    levels = ('DEBUG', 'INFO', 'WARNING', 'ERROR', 'CRITICAL')
    parser.add_argument('--log-level', default='INFO', choices=levels,
                        help='Logging level')
    subparsers = parser.add_subparsers(dest='command',
                                       help='Available commands')
    start_cmd = subparsers.add_parser('start', help='Start services')
    start_cmd.add_argument('name', metavar='NAME',
                           help='Name of service to start')
    stop_cmd = subparsers.add_parser('stop',
                                     help='Stop one or more services')
    stop_cmd.add_argument('names', metavar='NAME', nargs='+',
                           help='Name of service to stop')
    restart_cmd = subparsers.add_parser('restart',
   help='Restart one or more services')
    restart_cmd.add_argument('names', metavar='NAME', nargs='+',
                             help='Name of service to restart')
    options = parser.parse_args()
    # the code to dispatch commands could all be in this
    # of illustration only, we implement each command in
    try:
        mod = importlib.import_module(options.command)
        cmd = getattr(mod, 'command')
```

```

except (ImportError, AttributeError):
    print('Unable to find the code for command \'%s\'' % command)
    return 1
# Could get fancy here and load configuration from file
logging.basicConfig(level=options.log_level,
                    format='%(levelname)s %(name)s %(message)s',
                    datefmt='%m-%d-%Y %H:%M:%S')

cmd(options)

if __name__ == '__main__':
    sys.exit(main())

```

And the start, stop and restart commands can be implemented in separate modules, like so for starting:

```

# start.py
import logging

logger = logging.getLogger(__name__)

def command(options):
    logger.debug('About to start %s', options.name)
    # actually do the command processing here ...
    logger.info('Started the \'%s\' service.', options.name)

```

and thus for stopping:

```

# stop.py
import logging

logger = logging.getLogger(__name__)

def command(options):
    n = len(options.names)
    if n == 1:
        plural = ''
        services = '\'%s\'' % options.names[0]
    else:
        plural = 's'
        services = ', '.join('\'%s\'' % name for name in options.names)

```

```

        i = services.rfind(', ')
        services = services[:i] + ' and ' + services[i + 1:]
        logger.debug('About to stop %s', services)
        # actually do the command processing here ...
        logger.info('Stopped the %s service%s.', services, plural)

```

and similarly for restarting:

```

# restart.py
import logging

logger = logging.getLogger(__name__)

def command(options):
    n = len(options.names)
    if n == 1:
        plural = ''
        services = '\'%s\'' % options.names[0]
    else:
        plural = 's'
        services = ', '.join('\'%s\'' % name for name in options.names)
        i = services.rfind(', ')
        services = services[:i] + ' and ' + services[i + 1:]
        logger.debug('About to restart %s', services)
        # actually do the command processing here ...
        logger.info('Restarted the %s service%s.', services, plural)

```

If we run this application with the default log level, we get output like this:

```

$ python app.py start foo
INFO start Started the 'foo' service.

$ python app.py stop foo bar
INFO stop Stopped the 'foo' and 'bar' services.

$ python app.py restart foo bar baz
INFO restart Restarted the 'foo', 'bar' and 'baz' services.

```

The first word is the logging level, and the second word is the module or package name of the place where the event was logged.

If we change the logging level, then we can change the information sent to the log. For example, if we want more information:

```
$ python app.py --log-level DEBUG start foo
DEBUG start About to start foo
INFO start Started the 'foo' service.
```

```
$ python app.py --log-level DEBUG stop foo bar
DEBUG stop About to stop 'foo' and 'bar'
INFO stop Stopped the 'foo' and 'bar' services.
```

```
$ python app.py --log-level DEBUG restart foo bar baz
DEBUG restart About to restart 'foo', 'bar' and 'baz'
INFO restart Restarted the 'foo', 'bar' and 'baz' services.
```

And if we want less:

```
$ python app.py --log-level WARNING start foo
$ python app.py --log-level WARNING stop foo bar
$ python app.py --log-level WARNING restart foo bar baz
```

In this case, the commands don't print anything to the console, since nothing at `WARNING` level or above is logged by them.

## A Qt GUI for logging

A question that comes up from time to time is about how to log to a GUI application. The [Qt](https://www.qt.io/) framework is a popular cross-platform UI framework with Python bindings using [PySide2](https://pypi.org/project/PySide2/) or [PyQt5](https://pypi.org/project/PyQt5/) libraries.

The following example shows how to log to a Qt GUI. This introduces a simple `QtHandler` class which takes a callable, which should be a slot in the main thread that does GUI updates. A worker thread is also created to show how you can log to the GUI from both the UI itself (via a button for manual logging) as well as a

worker thread doing work in the background (here, just logging messages at random levels with random short delays in between).

The worker thread is implemented using Qt's `QThread` class rather than the `threading` module, as there are circumstances where one has to use `QThread`, which offers better integration with other Qt components.

The code should work with recent releases of either `PySide2` or `PyQt5`. You should be able to adapt the approach to earlier versions of Qt. Please refer to the comments in the code snippet for more detailed information.

```
import datetime
import logging
import random
import sys
import time

# Deal with minor differences between PySide2 and PyQt5
try:
    from PySide2 import QtCore, QtGui, QtWidgets
    Signal = QtCore.Signal
    Slot = QtCore.Slot
except ImportError:
    from PyQt5 import QtCore, QtGui, QtWidgets
    Signal = QtCore.pyqtSignal
    Slot = QtCore.pyqtSlot

logger = logging.getLogger(__name__)

#
# Signals need to be contained in a QObject or subclass
# initialized.
#
class Signaller(QtCore.QObject):
    signal = Signal(str, logging.LogRecord)
```

```

#
# Output to a Qt GUI is only supposed to happen on the m
# handler is designed to take a slot function which is s
# thread. In this example, the function takes a string a
# formatted log message, and the log record which genera
# string is just a convenience - you could format a stri
# you like in the slot function itself.
#
# You specify the slot function to do whatever GUI updat
# doesn't know or care about specific UI elements.
#
class QtHandler(logging.Handler):
    def __init__(self, slotfunc, *args, **kwargs):
        super().__init__(*args, **kwargs)
        self.signaller = Signaller()
        self.signaller.signal.connect(slotfunc)

    def emit(self, record):
        s = self.format(record)
        self.signaller.signal.emit(s, record)

#
# This example uses QThreads, which means that the threa
# are named something like "Dummy-1". The function below
# current thread.
#
def ctname():
    return QtCore.QThread.currentThread().objectName()

#
# Used to generate random levels for logging.
#
LEVELS = (logging.DEBUG, logging.INFO, logging.WARNING,
          logging.CRITICAL)

#

```

```

# This worker class represents work that is done in a thread
# main thread. The way the thread is kicked off to do work
# that connects to a slot in the worker.
#
# Because the default threadName value in the LogRecord
# a qThreadName which contains the QThread name as computed
# value in an "extra" dictionary which is used to update
# QThread name.
#
# This example worker just outputs messages sequentially
# random delays of the order of a few seconds.
#
class Worker(QtCore.QObject):
    @Slot()
    def start(self):
        extra = {'qThreadName': ctname() }
        logger.debug('Started work', extra=extra)
        i = 1
        # Let the thread run until interrupted. This allows for
        # thread termination.
        while not QtCore.QThread.currentThread().isInterrupted():
            delay = 0.5 + random.random() * 2
            time.sleep(delay)
            level = random.choice(LEVELS)
            logger.log(level, 'Message after delay of %3s' % delay)
            i += 1

#
# Implement a simple UI for this cookbook example. This
#
# * A read-only text edit window which holds formatted log messages
# * A button to start work and log stuff in a separate thread
# * A button to log something from the main thread
# * A button to clear the log window
#
class Window(QtWidgets.QWidget):

    COLORS = {

```

```

        logging.DEBUG: 'black',
        logging.INFO: 'blue',
        logging.WARNING: 'orange',
        logging.ERROR: 'red',
        logging.CRITICAL: 'purple',
    }

def __init__(self, app):
    super().__init__()
    self.app = app
    self.textedit = te = QtWidgets.QPlainTextEdit(self)
    # Set whatever the default monospace font is for Qt
    f = QtGui.QFont('nosuchfont')
    f.setStyleHint(f.Monospace)
    te.setFont(f)
    te.setReadOnly(True)
    PB = QtWidgets.QPushButton
    self.work_button = PB('Start background work', self)
    self.log_button = PB('Log a message at a random time', self)
    self.clear_button = PB('Clear log window', self)
    self.handler = h = QtHandler(self.update_status)
    # Remember to use qThreadName rather than threadName
    fs = '%(asctime)s %(qThreadName)-12s %(levelname)s\n'
    formatter = logging.Formatter(fs)
    h.setFormatter(formatter)
    logger.addHandler(h)
    # Set up to terminate the QThread when we exit
    app.aboutToQuit.connect(self.force_quit)

    # Lay out all the widgets
    layout = QtWidgets.QVBoxLayout(self)
    layout.addWidget(te)
    layout.addWidget(self.work_button)
    layout.addWidget(self.log_button)
    layout.addWidget(self.clear_button)
    self.setFixedSize(900, 400)

    # Connect the non-worker slots and signals

```

```

self.log_button.clicked.connect(self.manual_update)
self.clear_button.clicked.connect(self.clear_data)

# Start a new worker thread and connect the slot
self.start_thread()
self.work_button.clicked.connect(self.worker.start)
# Once started, the button should be disabled
self.work_button.clicked.connect(lambda : self.worker.stop)

def start_thread(self):
    self.worker = Worker()
    self.worker_thread = QtCore.QThread()
    self.worker.setObjectName('Worker')
    self.worker_thread.setObjectName('WorkerThread')
    self.worker.moveToThread(self.worker_thread)
    # This will start an event loop in the worker thread
    self.worker_thread.start()

def kill_thread(self):

    example = Window(app)
    example.show()
    sys.exit(app.exec_())

if __name__=='__main__':
    main()

```

## Logging to syslog with RFC5424 support

Although [RFC 5424](https://datatracker.ietf.org/doc/html/rfc5424.html) [https://datatracker.ietf.org/doc/html/rfc5424.html] dates from 2009, most syslog servers are configured by default to use the older [RFC 3164](https://datatracker.ietf.org/doc/html/rfc3164.html) [https://datatracker.ietf.org/doc/html/rfc3164.html], which hails from 2001. When `logging` was added to Python in 2003, it supported the earlier (and only existing) protocol at the time. Since RFC5424 came out, as there has not been widespread deployment of it in syslog servers, the [SysLogHandler](#)

functionality has not been updated.

RFC 5424 contains some useful features such as support for structured data, and if you need to be able to log to a syslog server with support for it, you can do so with a subclassed handler which looks something like this:

```
import datetime
import logging.handlers
import re
import socket
import time

class SysLogHandler5424(logging.handlers.SysLogHandler):

    tz_offset = re.compile(r'([+-]\d{2})(\d{2})$')
    escaped = re.compile(r'([\\"\\])')

    def __init__(self, *args, **kwargs):
        self.msgid = kwargs.pop('msgid', None)
        self.appname = kwargs.pop('appname', None)
        super().__init__(*args, **kwargs)

    def format(self, record):
        version = 1
        asctime = datetime.datetime.fromtimestamp(record
            m = self.tz_offset.match(time.strftime('%z'))
            has_offset = False
            if m and time.timezone:
                hrs, mins = m.groups()
                if int(hrs) or int(mins):
                    has_offset = True
            if not has_offset:
                asctime += 'Z'
            else:
                asctime += f'{hrs}:{mins}'
        try:
            hostname = socket.gethostname()
        except Exception:
```

```

        hostname = '-'
        appname = self.appname or '-'
        procid = record.process
        msgid = '-'
        msg = super().format(record)
        sdata = '-'
        if hasattr(record, 'structured_data'):
            sd = record.structured_data
            # This should be a dict where the keys are S
            # dict mapping PARAM-NAME to PARAM-VALUE (re
            # mean)
            # There's no error checking here - it's pure
            # can adapt this code for use in production
            parts = []

            def replacer(m):
                g = m.groups()
                return '\\\\' + g[0]

            for sdid, dv in sd.items():
                part = f'[{sdid}]'
                for k, v in dv.items():
                    s = str(v)
                    s = self.escaped.sub(replacer, s)
                    part += f' {k}="{s}"'
                part += ']'
                parts.append(part)
            sdata = ''.join(parts)
        return f'{version} {asctime} {hostname} {appname}

```

You'll need to be familiar with RFC 5424 to fully understand the above code, and it may be that you have slightly different needs (e.g. for how you pass structural data to the log). Nevertheless, the above should be adaptable to your specific needs. With the above handler, you'd pass structured data using something like this:

```

sd = {
    'foo@12345': {'bar': 'baz', 'baz': 'bozz', 'fizz': r
    'foo@54321': {'rab': 'baz', 'zab': 'bozz', 'zzif': r

```

```
}  
extra = {'structured_data': sd}  
i = 1  
logger.debug('Message %d', i, extra=extra)
```

## How to treat a logger like an output stream

Sometimes, you need to interface to a third-party API which expects a file-like object to write to, but you want to direct the API's output to a logger. You can do this using a class which wraps a logger with a file-like API. Here's a short script illustrating such a class:

```
import logging  
  
class LoggerWriter:  
    def __init__(self, logger, level):  
        self.logger = logger  
        self.level = level  
  
    def write(self, message):  
        if message != '\n': # avoid printing bare newlines  
            self.logger.log(self.level, message)  
  
    def flush(self):  
        # doesn't actually do anything, but might be expected  
        # object - so optional depending on your situation  
        pass  
  
    def close(self):  
        # doesn't actually do anything, but might be expected  
        # object - so optional depending on your situation  
        # to set a flag so that later calls to write raise an error  
        pass  
  
def main():  
    logging.basicConfig(level=logging.DEBUG)  
    logger = logging.getLogger('demo')
```

```
info_fp = LoggerWriter(logger, logging.INFO)
debug_fp = LoggerWriter(logger, logging.DEBUG)
print('An INFO message', file=info_fp)
print('A DEBUG message', file=debug_fp)

if __name__ == "__main__":
    main()
```

When this script is run, it prints

```
INFO:demo:An INFO message
DEBUG:demo:A DEBUG message
```

You could also use `LoggerWriter` to redirect `sys.stdout` and `sys.stderr` by doing something like this:

```
import sys

sys.stdout = LoggerWriter(logger, logging.INFO)
sys.stderr = LoggerWriter(logger, logging.WARNING)
```

You should do this *after* configuring logging for your needs. In the above example, the `basicConfig()` call does this (using the `sys.stderr` value *before* it is overwritten by a `LoggerWriter` instance). Then, you'd get this kind of result:

```
>>> print('Foo')
INFO:demo:Foo
>>> print('Bar', file=sys.stderr)
WARNING:demo:Bar
>>>
```

Of course, the examples above show output according to the format used by `basicConfig()`, but you can use a different formatter when you configure logging.

Note that with the above scheme, you are somewhat at the mercy of buffering and the sequence of write calls which you are intercepting. For example, with the definition of `LoggerWriter` above, if you have the snippet

```
sys.stderr = LoggerWriter(logger, logging.WARNING)
1 / 0
```

then running the script results in

```
WARNING:demo:Traceback (most recent call last):
```

```
WARNING:demo:  File "/home/runner/cookbook-loggerwriter/
```

```
WARNING:demo:
```

```
WARNING:demo:main()
```

```
WARNING:demo:  File "/home/runner/cookbook-loggerwriter/
```

```
WARNING:demo:
```

```
WARNING:demo:1 / 0
```

```
WARNING:demo:ZeroDivisionError
```

```
WARNING:demo::
```

```
WARNING:demo:division by zero
```

As you can see, this output isn't ideal. That's because the underlying code which writes to `sys.stderr` makes multiple writes, each of which results in a separate logged line (for example, the last three lines above). To get around this problem, you need to buffer things and only output log lines when newlines are seen. Let's use a slightly better implementation of `LoggerWriter`:

```
class BufferingLoggerWriter(LoggerWriter):
    def __init__(self, logger, level):
        super().__init__(logger, level)
        self.buffer = ''

    def write(self, message):
        if '\n' not in message:
            self.buffer += message
        else:
            parts = message.split('\n')
            if self.buffer:
                s = self.buffer + parts.pop(0)
                self.logger.log(self.level, s)
```

```
self.buffer = parts.pop()
for part in parts:
    self.logger.log(self.level, part)
```

This just buffers up stuff until a newline is seen, and then logs complete lines. With this approach, you get better output:

```
WARNING:demo:Traceback (most recent call last):
WARNING:demo:  File "/home/runner/cookbook-loggerwriter/
WARNING:demo:    main()
WARNING:demo:  File "/home/runner/cookbook-loggerwriter/
WARNING:demo:    1/0
WARNING:demo:ZeroDivisionError: division by zero
```

## Patterns to avoid

Although the preceding sections have described ways of doing things you might need to do or deal with, it is worth mentioning some usage patterns which are *unhelpful*, and which should therefore be avoided in most cases. The following sections are in no particular order.

### Opening the same log file multiple times

On Windows, you will generally not be able to open the same file multiple times as this will lead to a “file is in use by another process” error. However, on POSIX platforms you’ll not get any errors if you open the same file multiple times. This could be done accidentally, for example by:

- Adding a file handler more than once which references the same file (e.g. by a copy/paste/forget-to-change error).
- Opening two files that look different, as they have different names, but are the same because one is a symbolic link to the other.
- Forking a process, following which both parent and child have a reference to the same file. This might be through use of the [multiprocessing](#) module, for example.

Opening a file multiple times might *appear* to work most of the

time, but can lead to a number of problems in practice:

- Logging output can be garbled because multiple threads or processes try to write to the same file. Although logging guards against concurrent use of the same handler instance by multiple threads, there is no such protection if concurrent writes are attempted by two different threads using two different handler instances which happen to point to the same file.
- An attempt to delete a file (e.g. during file rotation) silently fails, because there is another reference pointing to it. This can lead to confusion and wasted debugging time - log entries end up in unexpected places, or are lost altogether. Or a file that was supposed to be moved remains in place, and grows in size unexpectedly despite size-based rotation being supposedly in place.

Use the techniques outlined in [Logging to a single file from multiple processes](#) to circumvent such issues.

## Using loggers as attributes in a class or passing them as parameters

While there might be unusual cases where you'll need to do this, in general there is no point because loggers are singletons. Code can always access a given logger instance by name using `logging.getLogger(name)`, so passing instances around and holding them as instance attributes is pointless. Note that in other languages such as Java and C#, loggers are often static class attributes. However, this pattern doesn't make sense in Python, where the module (and not the class) is the unit of software decomposition.

## Adding handlers other than `NullHandler` to a logger in a library

Configuring logging by adding handlers, formatters and filters is the responsibility of the application developer, not the library developer. If you are maintaining a library, ensure that you don't add handlers to any of your loggers other than a `NullHandler`

instance.

## Creating a lot of loggers

Loggers are singletons that are never freed during a script execution, and so creating lots of loggers will use up memory which can't then be freed. Rather than create a logger per e.g. file processed or network connection made, use the [existing mechanisms](#) for passing contextual information into your logs and restrict the loggers created to those describing areas within your application (generally modules, but occasionally slightly more fine-grained than that).

# Regular Expression HOWTO

Author

A.M. Kuchling <[amk@amk.ca](mailto:amk@amk.ca)>

## Abstract

This document is an introductory tutorial to using regular expressions in Python with the `re` module. It provides a gentler introduction than the corresponding section in the Library Reference.

## Introduction

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the `re` module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn’t covered in this document, because it requires that you have a good understanding of the matching engine’s internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular

expressions. There are also tasks that *can* be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.

## Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

## Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression `test` will match the string `test` exactly. (You can enable a case-insensitive mode that would let this RE match `Test` or `TEST` as well; more about this later.)

There are exceptions to this rule; some characters are special *metacharacters*, and don't match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here's a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

`. ^ $ * + ? { } [ ] \ | ( )`

The first metacharacters we'll look at are `[` and `]`. They're used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of

characters can be indicated by giving two characters and separating them by a `-`. For example, `[abc]` will match any of the characters `a`, `b`, or `c`; this is the same as `[a-c]`, which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be `[a-z]`.

Metacharacters (except `\`) are not active inside classes. For example, `[akm$]` will match any of the characters `'a'`, `'k'`, `'m'`, or `'$'`; `'$'` is usually a metacharacter, but inside a character class it's stripped of its special nature.

You can match the characters not listed within the class by *complementing* the set. This is indicated by including a `^` as the first character of the class. For example, `[^5]` will match any character except `'5'`. If the caret appears elsewhere in a character class, it does not have special meaning. For example: `[5^]` will match either a `'5'` or a `'^'`.

Perhaps the most important metacharacter is the backslash, `\`. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It's also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a `[` or `\`, you can precede them with a backslash to remove their special meaning: `\[` or `\\`.

Some of the special sequences beginning with `'\'` represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn't whitespace.

Let's take an example: `\w` matches any alphanumeric character. If the regex pattern is expressed in bytes, this is equivalent to the class `[a-zA-Z0-9_]`. If the regex pattern is a string, `\w` will match all the characters marked as letters in the Unicode database provided by the `unicodedata` module. You can use the more restricted definition of `\w` in a string pattern by supplying the `re.ASCII` flag when compiling the regular expression.

The following list of special sequences isn't complete. For a complete list of sequences and expanded class definitions for Unicode string patterns, see the last part of [Regular Expression](#)

[Syntax](#) in the Standard Library reference. In general, the Unicode versions match any character that's in the appropriate category in the Unicode database.

`\d`

Matches any decimal digit; this is equivalent to the class `[0-9]`.

`\D`

Matches any non-digit character; this is equivalent to the class `[^0-9]`.

`\s`

Matches any whitespace character; this is equivalent to the class `[\t\n\r\f\v]`.

`\S`

Matches any non-whitespace character; this is equivalent to the class `[^\t\n\r\f\v]`.

`\w`

Matches any alphanumeric character; this is equivalent to the class `[a-zA-Z0-9_]`.

`\W`

Matches any non-alphanumeric character; this is equivalent to the class `[^a-zA-Z0-9_]`.

These sequences can be included inside a character class. For example, `[\s,.]` is a character class that will match any whitespace character, or `,` or `.`.

The final metacharacter in this section is `.`. It matches anything except a newline character, and there's an alternate mode ([re.DOTALL](#)) where it will match even a newline. `.` is often used where you want to match “any character”.

## Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn't already possible with the

methods available on strings. However, if that was the only additional capability of regexes, they wouldn't be much of an advance. Another capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we'll look at is `*`. `*` doesn't match the literal character `'*'`; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, `ca*t` will match `'ct'` (0 `'a'` characters), `'cat'` (1 `'a'`), `'caaat'` (3 `'a'` characters), and so forth.

Repetitions such as `*` are *greedy*; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don't match, the matching engine will then back up and try again with fewer repetitions.

A step-by-step example will make this more obvious. Let's consider the expression `a[bcd]*b`. This matches the letter `'a'`, zero or more letters from the class `[bcd]`, and finally ends with a `'b'`. Now imagine matching this RE against the string `'abcbcd'`.

### **Explanation**

---

The `a` in the RE matches.

---

The engine matches `[bcd]*`, going as far as it can, which is to the end of the string.

---

The engine tries to match `b`, but the current position is at the end of the string, so it fails.

---

Back up, so that `[bcd]*` matches one less character.

---

Try again, but the current position is at the last character, which is a `'d'`.

---

Back up again, so that `[bcd]*` is only matching `bc`.

---

Try `b` again. This time the character at the current position is `'b'`, so it succeeds.

---

The end of the RE has now been reached, and it has matched `'abcb'`. This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for `[bcd]*`, and if that subsequently

fails, the engine will conclude that the string doesn't match the RE at all.

Another repeating metacharacter is `+`, which matches one or more times. Pay careful attention to the difference between `*` and `+`; `*` matches *zero* or more times, so whatever's being repeated may not be present at all, while `+` requires at least *one* occurrence. To use a similar example, `ca+t` will match `'cat'` (1 'a'), `'caaat'` (3 'a's), but won't match `'ct'`.

There are two more repeating operators or quantifiers. The question mark character, `?`, matches either once or zero times; you can think of it as marking something as being optional. For example, `home-?brew` matches either `'homebrew'` or `'home-brew'`.

The most complicated quantifier is `{m,n}`, where *m* and *n* are decimal integers. This quantifier means there must be at least *m* repetitions, and at most *n*. For example, `a/{1,3}b` will match `'a/b'`, `'a//b'`, and `'a///b'`. It won't match `'ab'`, which has no slashes, or `'a////b'`, which has four.

You can omit either *m* or *n*; in that case, a reasonable value is assumed for the missing value. Omitting *m* is interpreted as a lower limit of 0, while omitting *n* results in an upper bound of infinity.

Readers of a reductionist bent may notice that the three other quantifiers can all be expressed using this notation. `{0,}` is the same as `*`, `{1,}` is equivalent to `+`, and `{0,1}` is the same as `?`. It's better to use `*`, `+`, or `?` when you can, simply because they're shorter and easier to read.

## Using Regular Expressions

Now that we've looked at some simple regular expressions, how do we actually use them in Python? The `re` module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

### Compiling Regular Expressions

Regular expressions are compiled into pattern objects, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```
>>> import re
>>> p = re.compile('ab*')
>>> p
re.compile('ab*')
```

`re.compile()` also accepts an optional *flags* argument, used to enable various special features and syntax variations. We'll go over the available settings later, but for now a single example will do:

```
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to `re.compile()` as a string. REs are handled as strings because regular expressions aren't part of the core Python language, and no special syntax was created for expressing them. (There are applications that don't need REs at all, so there's no need to bloat the language specification by including them.) Instead, the `re` module is simply a C extension module included with Python, just like the `socket` or `zlib` modules.

Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.

## The Backslash Plague

As stated earlier, regular expressions use the backslash character (`'\'`) to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python's usage of the same character for the same purpose in string literals.

Let's say you want to write a RE that matches the string `\section`, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string `\\section`. The resulting string that must be passed to `re.compile()` must be `\\section`. However, to express this as

a Python string literal, both backslashes must be escaped *again*.

## Characters

---

Text string to be matched
Escaped backslash for <code>re.compile()</code>
Escaped backslashes for a string literal

---

In short, to match a literal backslash, one has to write `'\\\\'` as the RE string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.

The solution is to use Python's raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with `'r'`, so `r"\n"` is a two-character string containing `'\'` and `'n'`, while `"\n"` is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

In addition, special escape sequences that are valid in regular expressions, but not valid as Python string literals, now result in a **DeprecationWarning** and will eventually become a **SyntaxError**, which means the sequences will be invalid if raw string notation or escaping the backslashes isn't used.

## Regular string

---

<code>r"ab*"</code>
<code>r"\\section"</code>
<code>r"\\w+\\\$\\\$\\\$1"</code>

---

## Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? Pattern objects have several methods and attributes. Only the most significant ones will be covered here; consult the **re** docs for a complete listing.

## Methods/Attribute

---

Determine if the RE matches at the beginning of the string.
-------------------------------------------------------------

---

**Search through** a string, looking for any location where this RE matches.

---

**Find all substrings** where the RE matches, and returns them as a list.

---

**Find all substrings** where the RE matches, and returns them as an iterator.

---

**match()** and **search()** return `None` if no match can be found. If they're successful, a **match object** instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the **re** module.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the **re** module, and compile a RE:

```
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
re.compile('[a-z]+')
```

Now, you can try matching various strings against the RE `[a-z]+`. An empty string shouldn't match at all, since `+` means 'one or more repetitions'. **match()** should return `None` in this case, which will cause the interpreter to print no output. You can explicitly print the result of **match()** to make this clear.

```
>>> p.match("")
>>> print(p.match(""))
None
```

Now, let's try it on a string that it should match, such as `tempo`. In this case, **match()** will return a **match object**, so you should store the result in a variable for later use.

```
>>> m = p.match('tempo')
>>> m
<re.Match object; span=(0, 5), match='tempo'>
```

Now you can query the [match object](#) for information about the matching string. Match object instances also have several methods and attributes; the most important ones are:

Method/Attribute
<b>Return</b> the string matched by the RE
<b>Return</b> the starting position of the match
<b>Return</b> the ending position of the match
<b>Return</b> a tuple containing the (start, end) positions of the match

Trying these methods will soon clarify their meaning:

```
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

**group()** returns the substring that was matched by the RE.  
**start()** and **end()** return the starting and ending index of the match. **span()** returns both start and end indexes in a single tuple. Since the **match()** method only checks if the RE matches at the start of a string, **start()** will always be zero. However, the **search()** method of patterns scans through the string, so the match may not start at zero in that case.

```
>>> print(p.match('::: message'))
None
>>> m = p.search('::: message'); print(m)
<re.Match object; span=(4, 11), match='message'>
>>> m.group()
'message'
>>> m.span()
(4, 11)
```

In actual programs, the most common style is to store the [match object](#) in a variable, and then check if it was `None`. This usually looks like:

```

p = re.compile( ... )
m = p.match( 'string goes here' )
if m:
    print('Match found: ', m.group())
else:
    print('No match')

```

Two pattern methods return all of the matches for a pattern.

**findall()** returns a list of matching strings:

```

>>> p = re.compile(r'\d+')
>>> p.findall('12 drummers drumming, 11 pipers piping, 10
['12', '11', '10']

```

The `r` prefix, making the literal a raw string literal, is needed in this example because escape sequences in a normal “cooked” string literal that are not recognized by Python, as opposed to regular expressions, now result in a **DeprecationWarning** and will eventually become a **SyntaxError**. See [The Backslash Plague](#).

**findall()** has to create the entire list before it can be returned as the result. The **finditer()** method returns a sequence of **match object** instances as an **iterator**:

```

>>> iterator = p.finditer('12 drummers drumming, 11 ...
>>> iterator
<callable_iterator object at 0x...>
>>> for match in iterator:
...     print(match.span())
...
(0, 2)
(22, 24)
(29, 31)

```

## Module-Level Functions

You don’t have to create a pattern object and call its methods; the **re** module also provides top-level functions called **match()**, **search()**, **findall()**, **sub()**, and so forth. These functions take the same arguments as the corresponding pattern method with

the RE string added as the first argument, and still return either `None` or a `match object` instance.

```
>>> print(re.match(r'From\s+', 'Fromage amk'))
None
>>> re.match(r'From\s+', 'From amk Thu May 14 19:12:10 1998')
<re.Match object; span=(0, 5), match='From ' >
```

Under the hood, these functions simply create a pattern object for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE won't need to parse the pattern again and again.

Should you use these module-level functions, or should you get the pattern and call its methods yourself? If you're accessing a regex within a loop, pre-compiling it will save a few function calls. Outside of loops, there's not much difference thanks to the internal cache.

## Compilation Flags

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the `re` module under two names, a long name such as `IGNORECASE` and a short, one-letter form such as `I`. (If you're familiar with Perl's pattern modifiers, the one-letter forms use the same letters; the short form of `re.VERBOSE` is `re.X`, for example.) Multiple flags can be specified by bitwise OR-ing them; `re.I | re.M` sets both the `I` and `M` flags, for example.

Here's a table of the available flags, followed by a more detailed explanation of each one.

### Magnifying

---

**Makes several escapes like `\w`, `\b`, `\s` and `\d` match only on ASCII characters with the respective property.**

---

**Makes `.` match any character, including newlines.**

---

**Does case-insensitive matches.**

---

**Does locale-aware match.**

---

**Multi-line matching, affecting `^` and `$`.**

---

**Enables verbose (or extended) syntax, which can be organized more cleanly and**

---

---

understandably.

---

re.I

re.IGNORECASE

Perform case-insensitive matching; character class and literal strings will match letters by ignoring case. For example, `[A-Z]` will match lowercase letters, too. Full Unicode matching also works unless the **ASCII** flag is used to disable non-ASCII matches. When the Unicode patterns `[a-z]` or `[A-Z]` are used in combination with the **IGNORECASE** flag, they will match the 52 ASCII letters and 4 additional non-ASCII letters: ‘İ’ (U+0130, Latin capital letter I with dot above), ‘ı’ (U+0131, Latin small letter dotless i), ‘ſ’ (U+017F, Latin small letter long s) and ‘K’ (U+212A, Kelvin sign). Spam will match ‘Spam’, ‘spam’, ‘spAM’, or ‘ſpam’ (the latter is matched only in Unicode mode). This lowercasing doesn’t take the current locale into account; it will if you also set the **LOCALE** flag.

re.L

re.LOCALE

Make `\w`, `\W`, `\b`, `\B` and case-insensitive matching dependent on the current locale instead of the Unicode database.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you’re processing encoded French text, you’d want to be able to write `\w+` to match words, but `\w` only matches the character class `[A-Za-z]` in bytes patterns; it won’t match bytes corresponding to `é` or `ç`. If your system is configured properly and a French locale is selected, certain C functions will tell the program that the byte corresponding to `é` should also be considered a letter. Setting the **LOCALE** flag when compiling a regular expression will cause the resulting compiled object to use these C functions for `\w`; this is slower, but also enables `\w+` to match French words as you’d expect. The use of this flag is discouraged in Python 3 as the locale mechanism is very unreliable, it only handles one “culture” at a time, and it only works with 8-bit locales.

Unicode matching is already enabled by default in Python 3 for Unicode (str) patterns, and it is able to handle different locales/languages.

re.M

re.MULTILINE

(`^` and `$` haven't been explained yet; they'll be introduced in section [More Metacharacters](#).)

Usually `^` matches only at the beginning of the string, and `$` matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, `^` matches at the beginning of the string and at the beginning of each line within the string, immediately following each newline. Similarly, the `$` metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

re.S

re.DOTALL

Makes the `'.'` special character match any character at all, including a newline; without this flag, `'.'` will match anything *except* a newline.

re.A

re.ASCII

Make `\w`, `\W`, `\b`, `\B`, `\s` and `\S` perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

re.X

re.VERBOSE

This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE

more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a '#' that's neither in a character class or preceded by an unescaped backslash.

For example, here's a RE that uses `re.VERBOSE`; see how much easier it is to read?

```
charref = re.compile(r"""
    &[#]                # Start of a numeric entity ref
    (
        0[0-7]+         # Octal form
        | [0-9]+         # Decimal form
        | x[0-9a-fA-F]+  # Hexadecimal form
    )
    ;                   # Trailing semicolon
""", re.VERBOSE)
```

Without the verbose setting, the RE would look like this:

```
charref = re.compile("&#(0[0-7]+"
                    " | [0-9]+"
                    " | x[0-9a-fA-F]+) ; ")
```

In the above example, Python's automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it's still more difficult to understand than the version using `re.VERBOSE`.

## More Pattern Power

So far we've only covered a part of the features of regular expressions. In this section, we'll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

### More Metacharacters

There are some metacharacters that we haven't covered yet. Most of

them will be covered in this section.

Some of the remaining metacharacters to be discussed are *zero-width assertions*. They don't cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, `\b` is an assertion that the current position is located at a word boundary; the position isn't changed by the `\b` at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

|

Alternation, or the “or” operator. If *A* and *B* are regular expressions, `A|B` will match any string that matches either *A* or *B*. `|` has very low precedence in order to make it work reasonably when you're alternating multi-character strings. `Crow|Servo` will match either `'Crow'` or `'Servo'`, not `'Cro'`, a `'w'` or an `'S'`, and `'ervo'`.

To match a literal `'|'`, use `\|`, or enclose it inside a character class, as in `[|]`.

^

Matches at the beginning of lines. Unless the **MULTILINE** flag has been set, this will only match at the beginning of the string. In **MULTILINE** mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word `From` only at the beginning of a line, the RE to use is `^From`.

```
>>> print(re.search('^From', 'From Here to Eternity'))
<re.Match object; span=(0, 4), match='From'>
>>> print(re.search('^From', 'Reciting From Memory'))
None
```

To match a literal `'^'`, use `\^`.

\$

Matches at the end of a line, which is defined as either the

end of the string, or any location followed by a newline character.

```
>>> print(re.search('}$', '{block}'))
<re.Match object; span=(6, 7), match='}'>
>>> print(re.search('}$', '{block} '))
None
>>> print(re.search('}$', '{block}\n'))
<re.Match object; span=(6, 7), match='}'>
```

To match a literal '\$', use `\$` or enclose it inside a character class, as in `[$]`.

`\A`

Matches only at the start of the string. When not in **MULTILINE** mode, `\A` and `^` are effectively the same. In **MULTILINE** mode, they're different: `\A` still matches only at the beginning of the string, but `^` may match at any location inside the string that follows a newline character.

`\Z`

Matches only at the end of the string.

`\b`

Word boundary. This is a zero-width assertion that matches only at the beginning or end of a word. A word is defined as a sequence of alphanumeric characters, so the end of a word is indicated by whitespace or a non-alphanumeric character.

The following example matches `class` only when it's a complete word; it won't match when it's contained inside another word.

```
>>> p = re.compile(r'\bclass\b')
>>> print(p.search('no class at all'))
<re.Match object; span=(3, 8), match='class'>
>>> print(p.search('the declassified algorithm'))
None
>>> print(p.search('one subclass is'))
None
```

There are two subtleties you should remember when using this special sequence. First, this is the worst collision between Python's string literals and regular expression sequences. In Python's string literals, `\b` is the backspace character, ASCII value 8. If you're not using raw strings, then Python will convert the `\b` to a backspace, and your RE won't match as you expect it to. The following example looks the same as our previous RE, but omits the `'r'` in front of the RE string.

```
>>> p = re.compile('\bclass\b')
>>> print(p.search('no class at all'))
None
>>> print(p.search('\b' + 'class' + '\b'))
<re.Match object; span=(0, 7), match='\x08class\x08'
```

Second, inside a character class, where there's no use for this assertion, `\b` represents the backspace character, for compatibility with Python's string literals.

`\B`

Another zero-width assertion, this is the opposite of `\b`, only matching when the current position is not at a word boundary.

## Grouping

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a `': '`, like this:

```
From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com
```

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header

name, and another group which matches the header's value.

Groups are marked by the `'(, ')` metacharacters. `'(` and `)'` have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a quantifier, such as `*`, `+`, `?`, or `{m,n}`. For example, `(ab)*` will match zero or more repetitions of `ab`.

```
>>> p = re.compile('(ab)*')
>>> print(p.match('ababababab').span())
(0, 10)
```

Groups indicated with `'(, ')` also capture the starting and ending index of the text that they match; this can be retrieved by passing an argument to `group()`, `start()`, `end()`, and `span()`. Groups are numbered starting with 0. Group 0 is always present; it's the whole RE, so `match object` methods all have group 0 as their default argument. Later we'll see how to express groups that don't capture the span of text that they match.

```
>>> p = re.compile('(a)b')
>>> m = p.match('ab')
>>> m.group()
'ab'
>>> m.group(0)
'ab'
```

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

```
>>> p = re.compile('(a(b)c)d')
>>> m = p.match('abcd')
>>> m.group(0)
'abcd'
>>> m.group(1)
'abc'
>>> m.group(2)
'b'
```

`group()` can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those groups.

```
>>> m.group(2,1,2)
('b', 'abc', 'b')
```

The `groups()` method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

```
>>> m.groups()
('abc', 'b')
```

Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, `\1` will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise. Remember that Python's string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```
>>> p = re.compile(r'\b(\w+)\s+\1\b')
>>> p.search('Paris in the the spring').group()
'the the'
```

Backreferences like this aren't often useful for just searching through a string — there are few text formats which repeat data in this way — but you'll soon find out that they're *very* useful when performing string substitutions.

## Non-capturing and Named Groups

Elaborate REs may use many groups, both to capture substrings of interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we'll look at that first.

Perl 5 is well known for its powerful additions to standard regular expressions. For these new features the Perl developers couldn't choose new single-keystroke metacharacters or new special sequences beginning with `\` without making Perl's regular expressions confusingly different from standard REs. If they chose `&` as a new metacharacter, for example, old expressions would be assuming that `&` was a regular character and wouldn't have escaped it by writing `\&` or `[&]`.

The solution chosen by the Perl developers was to use `(? . . . )` as the extension syntax. `?` immediately after a parenthesis was a syntax error because the `?` would have nothing to repeat, so this didn't introduce any compatibility problems. The characters immediately after the `?` indicate what extension is being used, so `(?=foo)` is one thing (a positive lookahead assertion) and `(?:foo)` is something else (a non-capturing group containing the subexpression `foo`).

Python supports several of Perl's extensions and adds an extension syntax to Perl's extension syntax. If the first character after the question mark is a `P`, you know that it's an extension that's specific to Python.

Now that we've looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs.

Sometimes you'll want to use a group to denote a part of a regular expression, but aren't interested in retrieving the group's contents. You can make this fact explicit by using a non-capturing group: `(?: . . . )`, where you can replace the `. . .` with any other regular expression.

```
>>> m = re.match("([abc])+", "abc")
>>> m.groups()
('c',)
>>> m = re.match("(?:[abc])+", "abc")
>>> m.groups()
()
```

Except for the fact that you can't retrieve the contents of what the

group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as `*`, and nest it within other groups (capturing or non-capturing). `(?:...)` is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there's no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: `(?P<name>...)`. *name* is, obviously, the name of the group. Named groups behave exactly like capturing groups, and additionally associate a name with a group. The [match object](#) methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group's name. Named groups are still given numbers, so you can retrieve information about a group in two ways:

```
>>> p = re.compile(r'(?P<word>\b\w+\b)')
>>> m = p.search('((( Lots of punctuation )))')
>>> m.group('word')
'Lots'
>>> m.group(1)
'Lots'
```

Additionally, you can retrieve named groups as a dictionary with [groupdict\(\)](#):

```
>>> m = re.match(r'(?P<first>\w+) (?P<last>\w+)', 'Jane')
>>> m.groupdict()
{'first': 'Jane', 'last': 'Doe'}
```

Named groups are handy because they let you use easily remembered names, instead of having to remember numbers. Here's an example RE from the [imaplib](#) module:

```
InternalDate = re.compile(r'INTERNALDATE "')
```

```

r' (?P<day>[ 123] [0-9]) - (?P<mon>[A-Z] [a-z] [a-z]) -
r' (?P<year>[0-9] [0-9] [0-9] [0-9]) '
r' (?P<hour>[0-9] [0-9]) : (?P<min>[0-9] [0-9]) : (?P<
r' (?P<zonen>[-+]) (?P<zoneh>[0-9] [0-9]) (?P<zonen
r' ""')

```

It's obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `(...)\1` refers to the number of the group. There's naturally a variant that uses the group name instead of the number. This is another Python extension: `(?P=name)` indicates that the contents of the group called *name* should again be matched at the current point. The regular expression for finding doubled words, `\b(\w+)\s+\1\b` can also be written as `\b(?P<word>\w+)\s+(?P=word)\b`:

```

>>> p = re.compile(r'\b(?P<word>\w+)\s+(?P=word)\b')
>>> p.search('Paris in the the spring').group()
'the the'

```

## Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

`(?=...)`

Positive lookahead assertion. This succeeds if the contained regular expression, represented here by `...`, successfully matches at the current location, and fails otherwise. But, once the contained expression has been tried, the matching engine doesn't advance at all; the rest of the pattern is tried right where the assertion started.

`(?!...)`

Negative lookahead assertion. This is the opposite of the positive assertion; it succeeds if the contained expression *doesn't* match at the current position in the string.

To make this concrete, let's look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a `.`. For example, in `news.rc`, `news` is the base name, and `rc` is the filename's extension.

The pattern to match this is quite simple:

```
.*[.].*$
```

Notice that the `.` needs to be treated specially because it's a metacharacter, so it's inside a character class to only match that specific character. Also notice the trailing `$`; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches `foo.bar` and `autoexec.bat` and `sendmail.cf` and `printers.conf`.

Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not `bat`? Some incorrect attempts:

`.*[.][^b].*$` The first attempt above tries to exclude `bat` by requiring that the first character of the extension is not a `b`. This is wrong, because the pattern also doesn't match `foo.bar`.

```
.*[.]( [^b].. | .[^a]. | ..[^t] )$
```

The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn't `b`; the second character isn't `a`; or the third character isn't `t`. This accepts `foo.bar` and rejects `autoexec.bat`, but it requires a three-letter extension and won't accept a filename with a two-letter extension such as `sendmail.cf`. We'll complicate the pattern again in an effort to fix it.

```
.*[.]( [^b].??.? | .[^a]??.? | ..?[^t]? )$
```

In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as `sendmail.cf`.

The pattern's getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both `bat` and `exe` as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

`.*[.](?!bat$)[^.]*$` The negative lookahead means: if the expression `bat` doesn't match at this point, try the rest of the pattern; if `bat$` does match, the whole pattern will fail. The trailing `$` is required to ensure that something like `sample.batch`, where the extension only starts with `bat`, will be allowed. The `[^.]*` makes sure that the pattern works when there are multiple dots in the filename.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either `bat` or `exe`:

```
.*[.](?!bat$|exe$)[^.]*$
```

## Modifying Strings

Up to this point, we've simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following pattern methods:

Method/Attribute
<b>Split</b> the string into a list, splitting it wherever the RE matches
<b>Find</b> (all substrings where the RE matches, and replace them with a different string
<b>Do</b> the same thing as <b>sub()</b> , but returns the new string and the number of replacements

## Splitting Strings

The `split()` method of a pattern splits a string apart wherever the RE matches, returning a list of the pieces. It's similar to the `split()` method of strings but provides much more generality in the delimiters that you can split by; string `split()` only supports

splitting by whitespace or by a fixed string. As you'd expect, there's a module-level `re.split()` function, too.

```
.split(string[, maxsplit=0])
```

Split *string* by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If *maxsplit* is nonzero, at most *maxsplit* splits are performed.

You can limit the number of splits made, by passing a value for *maxsplit*. When *maxsplit* is nonzero, at most *maxsplit* splits will be made, and the remainder of the string is returned as the final element of the list. In the following example, the delimiter is any sequence of non-alphanumeric characters.

```
>>> p = re.compile(r'\W+')
>>> p.split('This is a test, short and sweet, of split()')
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', 'of']
>>> p.split('This is a test, short and sweet, of split()')
['This', 'is', 'a', 'test, short and sweet, of split().']
```

Sometimes you're not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```
>>> p = re.compile(r'\W+')
>>> p2 = re.compile(r'(\W+)')
>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
>>> p2.split('This... is a test.')
['This', '...', ' ', 'is', ' ', 'a', ' ', 'test', '.', '']
```

The module-level function `re.split()` adds the RE to be used as the first argument, but is otherwise the same.

```
>>> re.split(r'[\W]+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split(r'([\W]+)', 'Words, words, words.')
['Words', ' ', ' ', 'words', ' ', ' ', 'words', '.', '']
```

```
>>> re.split(r'[\W]+', 'Words, words, words.', 1)
['Words', 'words, words.']
```

## Search and Replace

Another common task is to find all the matches for a pattern, and replace them with a different string. The `sub()` method takes a replacement value, which can be either a string or a function, and the string to be processed.

```
.sub(replacement, string[, count=0])
```

Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in *string* by the replacement *replacement*. If the pattern isn't found, *string* is returned unchanged.

The optional argument *count* is the maximum number of pattern occurrences to be replaced; *count* must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here's a simple example of using the `sub()` method. It replaces colour names with the word `colour`:

```
>>> p = re.compile('(blue|white|red)')
>>> p.sub('colour', 'blue socks and red shoes')
'colour socks and colour shoes'
>>> p.sub('colour', 'blue socks and red shoes', count=1)
'colour socks and red shoes'
```

The `subn()` method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```
>>> p = re.compile('(blue|white|red)')
>>> p.subn('colour', 'blue socks and red shoes')
('colour socks and colour shoes', 2)
>>> p.subn('colour', 'no colours at all')
('no colours at all', 0)
```

Empty matches are replaced only when they're not adjacent to a previous empty match.

```
>>> p = re.compile('x*')
>>> p.sub('-', 'abxd')
'-a-b--d-'
```

If *replacement* is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted to a carriage return, and so forth. Unknown escapes such as `\&` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word `section` followed by a string enclosed in `{, }`, and changes `section` to `subsection`:

```
>>> p = re.compile('section{ ( [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}', 'section{First} section{second}')
'subsection{First} subsection{second}'
```

There's also a syntax for referring to named groups as defined by the `(?P<name>...)` syntax. `\g<name>` will use the substring matched by the group named `name`, and `\g<number>` uses the corresponding group number. `\g<2>` is therefore equivalent to `\2`, but isn't ambiguous in a replacement string such as `\g<2>0`. (`\20` would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character `'0'`.) The following substitutions are all equivalent, but use all three variations of the replacement string.

```
>>> p = re.compile('section{ (?P<name> [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}', 'section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<1>}', 'section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<name>}', 'section{First}')
'subsection{First}'
```

*replacement* can also be a function, which gives you even more

control. If *replacement* is a function, the function is called for every non-overlapping occurrence of *pattern*. On each call, the function is passed a **match object** argument for the match and can use this information to compute the desired replacement string and return it.

In the following example, the replacement function translates decimals into hexadecimal:

```
>>> def hexrepl(match):
...     "Return the hex string for a decimal number"
...     value = int(match.group())
...     return hex(value)
...
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for u
'Call 0xffd2 for printing, 0xc000 for user code.'
```

When using the module-level **re.sub()** function, the pattern is passed as the first argument. The pattern may be provided as an object or as a string; if you need to specify regular expression flags, you must either use a pattern object as the first parameter, or use embedded modifiers in the pattern string, e.g. `sub("(?i)b+", "x", "bbbb BBBB")` returns `'x x'`.

## Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn't intuitive and at times they don't behave the way you may expect them to. This section will point out some of the most common pitfalls.

### Use String Methods

Sometimes using the **re** module is a mistake. If you're matching a fixed string, or a single character class, and you're not using any **re** features such as the **IGNORECASE** flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they're

usually much faster, because the implementation is a single small C loop that's been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace `word` with `deed`. `re.sub()` seems like the function to use for this, but consider the `replace()` method. Note that `replace()` will also replace `word` inside words, turning `swordfish` into `sdeedfish`, but the naive RE `word` would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be `\bword\b`, in order to require that `word` have a word boundary on either side. This takes the job beyond `replace()`'s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character. You might do this with something like `re.sub('\n', ' ', S)`, but `translate()` is capable of doing both tasks and will be faster than any regular expression operation can be.

In short, before turning to the `re` module, consider whether your problem can be solved with a faster and simpler string method.

## **match() versus search()**

The `match()` function only checks if the RE matches at the beginning of the string while `search()` will scan forward through the string for a match. It's important to keep this distinction in mind. Remember, `match()` will only report a successful match which will start at 0; if the match wouldn't start at zero, `match()` will *not* report it.

```
>>> print(re.match('super', 'superstition').span())
(0, 5)
>>> print(re.match('super', 'insuperable'))
None
```

On the other hand, `search()` will scan forward through the string, reporting the first match it finds.

```
>>> print(re.search('super', 'superstition').span())
```

```
(0, 5)
>>> print(re.search('super', 'insuperable').span())
(2, 7)
```

Sometimes you'll be tempted to keep using `re.match()`, and just add `.*` to the front of your RE. Resist this temptation and use `re.search()` instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with `Crow` must match starting with a `'C'`. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a `'C'` is found.

Adding `.*` defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use `re.search()` instead.

## Greedy versus Non-Greedy

When repeating a regular expression, as in `a*`, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you're trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn't work because of the greedy nature of `.*`.

```
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print(re.match('<.*>', s).span())
(0, 32)
>>> print(re.match('<.*>', s).group())
<html><head><title>Title</title>
```

The RE matches the `'<'` in `'<html>'`, and the `.*` consumes the rest of the string. There's still more left in the RE, though, and the `>` can't match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the `>`. The final match extends from the `'<'` in `'<html>'` to

the `'>'` in `'</title>'`, which isn't what you want.

In this case, the solution is to use the non-greedy quantifiers `*?`, `+?`, `??`, or `{m,n}?`, which match as *little* text as possible. In the above example, the `'>'` is tried immediately after the first `'<'` matches, and when it fails, the engine advances a character at a time, retrying the `'>'` at every step. This produces just the right result:

```
>>> print(re.match('<.*?>', s).group())
<html>
```

(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you've written a regular expression that handles all of the possible cases, the patterns will be *very* complicated. Use an HTML or XML parser module for such tasks.)

## Using `re.VERBOSE`

By now you've probably noticed that regular expressions are a very compact notation, but they're not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the `re.VERBOSE` flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The `re.VERBOSE` flag has several effects. Whitespace in the regular expression that *isn't* inside a character class is ignored. This means that an expression such as `dog | cat` is equivalent to the less readable `dog|cat`, but `[a b]` will still match the characters `'a'`, `'b'`, or a space. In addition, you can also put comments inside a RE; comments extend from a `#` character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```
pat = re.compile(r"""
```

```

\s*           # Skip leading whitespace
(?P<header>[^\:]+) # Header name
\s* :        # Whitespace, and a colon
(?P<value>.*?)  # The header's value -- *? used to
                # lose the following trailing white
\s*$          # Trailing whitespace to end-of-line
""" , re.VERBOSE)

```

This is far more readable than:

```
pat = re.compile(r"\s*(?P<header>[^\:]+)\s*:(?P<value>.*?)")
```

## Feedback

Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or Problems you encountered that weren't covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl's *Mastering Regular Expressions*, published by O'Reilly. Unfortunately, it exclusively concentrates on Perl and Java's flavours of regular expressions, and doesn't contain any Python material at all, so it won't be useful as a reference for programming in Python. (The first edition covered Python's now-removed **regex** module, which won't help you much.) Consider checking it out from your library.

# Socket Programming HOWTO

Author

Gordon McMillan

## Abstract

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It's not really a tutorial - you'll still have work to do in getting things operational. It doesn't cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.

## Sockets

I'm only going to talk about INET (i.e. IPv4) sockets, but they account for at least 99% of the sockets in use. And I'll only talk about STREAM (i.e. TCP) sockets - unless you really know what you're doing (in which case this HOWTO isn't for you!), you'll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I'll start by talking about blocking sockets. You'll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that "socket" can mean a number of subtly different things, depending on context. So first, let's make a distinction between a "client" socket - an endpoint of a conversation, and a "server" socket, which is more like a switchboard operator. The client application (your browser, for example) uses "client" sockets exclusively; the web server it's talking to uses both "server" sockets and "client" sockets.

## History

Of the various forms of IPC, sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.

They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other schemes).

## Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```
# create an INET, STREAMing socket
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# now connect to the web server on port 80 - the normal
s.connect(("www.python.org", 80))
```

When the `connect` completes, the socket `s` can be used to send in a request for the text of the page. The same socket will read the reply, and then be destroyed. That's right, destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a “server socket”:

```
# create an INET, STREAMing socket
serversocket = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# bind the socket to a public host, and a well-known port
serversocket.bind((socket.gethostname(), 80))
# become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so

that the socket would be visible to the outside world. If we had used `s.bind('localhost', 80)` or `s.bind('127.0.0.1', 80)` we would still have a “server” socket, but one that was only visible within the same machine. `s.bind('', 80)` specifies that the socket is reachable by any address the machine happens to have.

A second thing to note: low number ports are usually reserved for “well known” services (HTTP, SNMP etc). If you’re playing around, use a nice high number (4 digits).

Finally, the argument to `listen` tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

Now that we have a “server” socket, listening on port 80, we can enter the mainloop of the web server:

```
while True:
    # accept connections from outside
    (clientsocket, address) = serversocket.accept()
    # now do something with the clientsocket
    # in this case, we'll pretend this is a threaded server
    ct = client_thread(clientsocket)
    ct.run()
```

There’s actually 3 general ways in which this loop could work - dispatching a thread to handle `clientsocket`, create a new process to handle `clientsocket`, or restructure this app to use non-blocking sockets, and multiplex between our “server” socket and any active `clientsockets` using `select`. More about that later. The important thing to understand now is this: this is *all* a “server” socket does. It doesn’t send any data. It doesn’t receive any data. It just produces “client” sockets. Each `clientsocket` is created in response to some *other* “client” socket doing a `connect()` to the host and port we’re bound to. As soon as we’ve created that `clientsocket`, we go back to listening for more connections. The two “clients” are free to chat it up - they are using some dynamically allocated port which will be recycled when the

conversation ends.

## IPC

If you need fast IPC between two processes on one machine, you should look into pipes or shared memory. If you do decide to use AF\_INET sockets, bind the “server” socket to `'localhost'`. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.

### See also

The [multiprocessing](#) integrates cross-platform IPC into a higher-level API.

## Using a Socket

The first thing to note, is that the web browser’s “client” socket and the web server’s “client” socket are identical beasts. That is, this is a “peer to peer” conversation. Or to put it another way, *as the designer, you will have to decide what the rules of etiquette are for a conversation*. Normally, the `connecting` socket starts the conversation, by sending in a request, or perhaps a signon. But that’s a design decision - it’s not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use `send` and `recv`, or you can transform your client socket into a file-like beast and use `read` and `write`. The latter is the way Java presents its sockets. I’m not going to talk about it here, except to warn you that you need to use `flush` on sockets. These are buffered “files”, and a common mistake is to `write` something, and then `read` for a reply. Without a `flush` in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come to the major stumbling block of sockets - `send` and `recv` operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they

return when the associated network buffers have been filled (`send`) or emptied (`recv`). They then tell you how many bytes they handled. It is *your* responsibility to call them again until your message has been completely dealt with.

When a `recv` returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data successfully; I'll talk more about this later.

A protocol like HTTP uses a socket for only one transfer. The client sends a request, then reads a reply. That's it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that *there is no EOT on a socket*. I repeat: if a socket `send` or `recv` returns after handling 0 bytes, the connection has been broken. If the connection has *not* been broken, you may wait on a `recv` forever, because the socket will *not* tell you that there's nothing more to read (for now). Now if you think about that a bit, you'll come to realize a fundamental truth of sockets: *messages must either be fixed length* (yuck), *or be delimited* (shrug), *or indicate how long they are* (much better), *or end by shutting down the connection*. The choice is entirely yours, (but some ways are righter than others).

Assuming you don't want to end the connection, the simplest solution is a fixed length message:

```
class MySocket:
    """demonstration class only
       - coded for clarity, not efficiency
    """

    def __init__(self, sock=None):
        if sock is None:
            self.sock = socket.socket(
                                socket.AF_INET, socket.SOCK_
            else:
```

```

        self.sock = sock

def connect(self, host, port):
    self.sock.connect((host, port))

def mysend(self, msg):
    totalsent = 0
    while totalsent < MSGLEN:
        sent = self.sock.send(msg[totalsent:])
        if sent == 0:
            raise RuntimeError("socket connection broken")
        totalsent = totalsent + sent

def myreceive(self):
    chunks = []
    bytes_recd = 0
    while bytes_recd < MSGLEN:
        chunk = self.sock.recv(min(MSGLEN - bytes_recd))
        if chunk == b'':
            raise RuntimeError("socket connection broken")
        chunks.append(chunk)
        bytes_recd = bytes_recd + len(chunk)
    return b''.join(chunks)

```

The sending code here is usable for almost any messaging scheme - in Python you send strings, and you can use `len()` to determine its length (even if it has embedded `\0` characters). It's mostly the receiving code that gets more complex. (And in C, it's not much worse, except you can't use `strlen` if the message has embedded `\0`s.)

The easiest enhancement is to make the first character of the message an indicator of message type, and have the type determine the length. Now you have two `recvs` - the first to get (at least) that first character so you can look up the length, and the second in a loop to get the rest. If you decide to go the delimited route, you'll be receiving in some arbitrary chunk size, (4096 or 8192 is frequently a good match for network buffer sizes), and scanning what you've received for a delimiter.

One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass `recv` an arbitrary chunk size, you may end up reading the start of a following message. You'll need to put that aside and hold onto it, until it's needed.

Prefixing the message with its length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5 characters in one `recv`. In playing around, you'll get away with it; but in high network loads, your code will very quickly break unless you use two `recv` loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that `send` does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Lets move on to cleaning up.

## Binary Data

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, [network byte order](https://en.wikipedia.org/wiki/Endianness#Networking) [https://en.wikipedia.org/wiki/Endianness#Networking] is big-endian, with the most significant byte first, so a 16 bit integer with the value 1 would be the two hex bytes 00 01. However, most common processors (x86/AMD64, ARM, RISC-V), are little-endian, with the least significant byte first - that same 1 would be 01 00.

Socket libraries have calls for converting 16 and 32 bit integers - `ntohl`, `htonl`, `ntohs`, `htons` where “n” means *network* and “h” means *host*, “s” means *short* and “l” means *long*. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around appropriately.

In these days of 64-bit machines, the ASCII representation of binary data is frequently smaller than the binary representation. That's because a surprising amount of the time, most integers have the value 0, or maybe 1. The string "0" would be two bytes, while a

full 64-bit integer would be 8. Of course, this doesn't fit well with fixed-length messages. Decisions, decisions.

## Disconnecting

Strictly speaking, you're supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean "I'm not going to send anymore, but I'll still listen", or "I'm not listening, good riddance!". Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server "This client is done sending, but can still receive." The server can detect "EOF" by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it's needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you're just being slow. *Please close your sockets when you're done.*

## When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. TCP is a reliable protocol, and it will wait a long, long time before giving up on a connection. If you're using threads, the entire thread is essentially dead. There's not much you can do about it. As long as you aren't doing something dumb, like holding a lock while doing a blocking read, the thread isn't really consuming much in the way of resources. Do *not* try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated

with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.

## Non-blocking Sockets

If you've understood the preceding, you already know most of what you need to know about the mechanics of using sockets. You'll still use the same calls, in much the same ways. It's just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(False)` to make it non-blocking. In C, it's more complex, (for one thing, you'll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable POSIX flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it's the exact same idea. You do this after creating the socket, but before using it. (Actually, if you're nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don't believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let's skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it's a piece of cake, but it's close enough to the C version that if you understand `select` in Python, you'll have little trouble with it in C:

```
ready_to_read, ready_to_write, in_error = \
    select.select(
        potential_readers,
        potential_writers,
        potential_errs,
        timeout)
```

You pass `select` three lists: the first contains all sockets that you

might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They contain the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return *something*. Same idea for the writable list. You'll be able to send *something*. Maybe not all you want to, but *something* is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a "server" socket, put it in the `potential_readers` list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the `potential_writers` list. If it shows up in the writable list, you have a decent chance that it has connected.

Actually, `select` can be handy even with blocking sockets. It's one way of determining whether you will block - the socket returns as readable when there's something in the buffers. However, this still doesn't help with the problem of determining whether the other end is done, or just busy with something else.

**Portability alert:** On Unix, `select` works both with the sockets and files. Don't try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets.

# Sorting HOW TO

## Author

Andrew Dalke and Raymond Hettinger

## Release

0.1

Python lists have a built-in `list.sort()` method that modifies the list in-place. There is also a `sorted()` built-in function that builds a new sorted list from an iterable.

In this document, we explore the various techniques for sorting data using Python.

## Sorting Basics

A simple ascending sort is very easy: just call the `sorted()` function. It returns a new sorted list:

```
>>> sorted([5, 2, 3, 1, 4])
[1, 2, 3, 4, 5]
```

You can also use the `list.sort()` method. It modifies the list in-place (and returns `None` to avoid confusion). Usually it's less convenient than `sorted()` - but if you don't need the original list, it's slightly more efficient.

```
>>> a = [5, 2, 3, 1, 4]
>>> a.sort()
>>> a
[1, 2, 3, 4, 5]
```

Another difference is that the `list.sort()` method is only defined for lists. In contrast, the `sorted()` function accepts any iterable.

```
>>> sorted({1: 'D', 2: 'B', 3: 'B', 4: 'E', 5: 'A'})
[1, 2, 3, 4, 5]
```

## Key Functions

Both `list.sort()` and `sorted()` have a `key` parameter to specify a function (or other callable) to be called on each list element prior to making comparisons.

For example, here's a case-insensitive string comparison:

```
>>> sorted("This is a test string from Andrew".split(),
['a', 'Andrew', 'from', 'is', 'string', 'test', 'This'])
```

The value of the `key` parameter should be a function (or other callable) that takes a single argument and returns a key to use for sorting purposes. This technique is fast because the key function is called exactly once for each input record.

A common pattern is to sort complex objects using some of the object's indices as keys. For example:

```
>>> student_tuples = [
...     ('john', 'A', 15),
...     ('jane', 'B', 12),
...     ('dave', 'B', 10),
... ]
>>> sorted(student_tuples, key=lambda student: student[2])
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The same technique works for objects with named attributes. For example:

```
>>> class Student:
...     def __init__(self, name, grade, age):
...         self.name = name
...         self.grade = grade
...         self.age = age
...     def __repr__(self):
...         return repr((self.name, self.grade, self.age))
```

```
>>> student_objects = [  
...     Student('john', 'A', 15),  
...     Student('jane', 'B', 12),  
...     Student('dave', 'B', 10),  
... ]  
>>> sorted(student_objects, key=lambda student: student.  
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)])
```

## Operator Module Functions

The key-function patterns shown above are very common, so Python provides convenience functions to make accessor functions easier and faster. The `operator` module has `itemgetter()`, `attrgetter()`, and a `methodcaller()` function.

Using those functions, the above examples become simpler and faster:

```
>>> from operator import itemgetter, attrgetter  
  
>>> sorted(student_tuples, key=itemgetter(2))  
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]  
  
>>> sorted(student_objects, key=attrgetter('age'))  
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The operator module functions allow multiple levels of sorting. For example, to sort by *grade* then by *age*:

```
>>> sorted(student_tuples, key=itemgetter(1,2))  
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]  
  
>>> sorted(student_objects, key=attrgetter('grade', 'age'))  
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]
```

## Ascending and Descending

Both `list.sort()` and `sorted()` accept a *reverse* parameter

with a boolean value. This is used to flag descending sorts. For example, to get the student data in reverse *age* order:

```
>>> sorted(student_tuples, key=itemgetter(2), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]

>>> sorted(student_objects, key=attrgetter('age'), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

## Sort Stability and Complex Sorts

Sorts are guaranteed to be [stable](https://en.wikipedia.org/wiki/Sorting_algorithm#Stability) [https://en.wikipedia.org/wiki/Sorting\_algorithm#Stability]. That means that when multiple records have the same key, their original order is preserved.

```
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2)]
>>> sorted(data, key=itemgetter(0))
[('blue', 1), ('blue', 2), ('red', 1), ('red', 2)]
```

Notice how the two records for *blue* retain their original order so that *('blue', 1)* is guaranteed to precede *('blue', 2)*.

This wonderful property lets you build complex sorts in a series of sorting steps. For example, to sort the student data by descending *grade* and then ascending *age*, do the *age* sort first and then sort again using *grade*:

```
>>> s = sorted(student_objects, key=attrgetter('age'))
>>> sorted(s, key=attrgetter('grade'), reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

This can be abstracted out into a wrapper function that can take a list and tuples of field and order to sort them on multiple passes.

```
>>> def multisort(xs, specs):
...     for key, reverse in reversed(specs):
...         xs.sort(key=attrgetter(key), reverse=reverse)
...     return xs

>>> multisort(list(student_objects), (('grade', True), ('age', False)))
```

```
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The [Timsort](https://en.wikipedia.org/wiki/Timsort) [https://en.wikipedia.org/wiki/Timsort] algorithm used in Python does multiple sorts efficiently because it can take advantage of any ordering already present in a dataset.

## Decorate-Sort-Undecorate

This idiom is called Decorate-Sort-Undecorate after its three steps:

- First, the initial list is decorated with new values that control the sort order.
- Second, the decorated list is sorted.
- Finally, the decorations are removed, creating a list that contains only the initial values in the new order.

For example, to sort the student data by *grade* using the DSU approach:

```
>>> decorated = [(student.grade, i, student) for i, student in student_list]
>>> decorated.sort()
>>> [student for grade, i, student in decorated]
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

This idiom works because tuples are compared lexicographically; the first items are compared; if they are the same then the second items are compared, and so on.

It is not strictly necessary in all cases to include the index *i* in the decorated list, but including it gives two benefits:

- The sort is stable – if two items have the same key, their order will be preserved in the sorted list.
- The original items do not have to be comparable because the ordering of the decorated tuples will be determined by at most the first two items. So for example the original list could contain complex numbers which cannot be sorted directly.

Another name for this idiom is [Schwartzian transform](https://en.wikipedia.org/wiki/Schwartzian_transform) [https://en.wikipedia.org/wiki/Schwartzian\_transform], after Randal L. Schwartz, who popularized it among Perl programmers.

Now that Python sorting provides key-functions, this technique is not often needed.

## Comparison Functions

Unlike key functions that return an absolute value for sorting, a comparison function computes the relative ordering for two inputs.

For example, a [balance scale](https://upload.wikimedia.org/wikipedia/commons/1/17/Balance_à_tabac_1850.JPG) [https://upload.wikimedia.org/wikipedia/commons/1/17/Balance\_à\_tabac\_1850.JPG] compares two samples giving a relative ordering: lighter, equal, or heavier. Likewise, a comparison function such as `cmp(a, b)` will return a negative value for less-than, zero if the inputs are equal, or a positive value for greater-than.

It is common to encounter comparison functions when translating algorithms from other languages. Also, some libraries provide comparison functions as part of their API. For example, `locale.strcoll()` is a comparison function.

To accommodate those situations, Python provides `functools.cmp_to_key` to wrap the comparison function to make it usable as a key function:

```
sorted(words, key=cmp_to_key(strcoll)) # locale-aware s
```

## Odds and Ends

- For locale aware sorting, use `locale.strxfrm()` for a key function or `locale.strcoll()` for a comparison function. This is necessary because “alphabetical” sort orderings can vary across cultures even if the underlying alphabet is the same.
- The *reverse* parameter still maintains sort stability (so that records with equal keys retain the original order). Interestingly, that effect can be simulated without the parameter by using the builtin `reversed()` function twice:

```
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('
```

```
>>> standard_way = sorted(data, key=itemgetter(0),
>>> double_reversed = list(reversed(sorted(reversed
>>> assert standard_way == double_reversed
>>> standard_way
[('red', 1), ('red', 2), ('blue', 1), ('blue', 2)]
```

- The sort routines use `<` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an `__lt__()` method:

```
>>> Student.__lt__ = lambda self, other: self.age <
>>> sorted(student_objects)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 14)]
```

However, note that `<` can fall back to using `__gt__()` if `__lt__()` is not implemented (see `object.__lt__()`).

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

```
>>> students = ['dave', 'john', 'jane']
>>> newgrades = {'john': 'F', 'jane': 'A', 'dave': 'C'}
>>> sorted(students, key=newgrades.__getitem__)
['jane', 'dave', 'john']
```

# Unicode HOWTO

## Release

1.12

This HOWTO discusses Python’s support for the Unicode specification for representing textual data, and explains various problems that people commonly encounter when trying to work with Unicode.

## Introduction to Unicode

### Definitions

Today’s programs need to be able to handle a wide variety of characters. Applications are often internationalized to display messages and output in a variety of user-selectable languages; the same program might need to output an error message in English, French, Japanese, Hebrew, or Russian. Web content can be written in any of these languages and can also include a variety of emoji symbols. Python’s string type uses the Unicode Standard for representing characters, which lets Python programs work with all these different possible characters.

Unicode (<https://www.unicode.org/>) is a specification that aims to list every character used by human languages and give each character its own unique code. The Unicode specifications are continually revised and updated to add new languages and symbols.

A **character** is the smallest possible component of a text. ‘A’, ‘B’, ‘C’, etc., are all different characters. So are ‘È’ and ‘Í’. Characters vary depending on the language or context you’re talking about. For example, there’s a character for “Roman Numeral One”, ‘I’, that’s separate from the uppercase letter ‘I’. They’ll usually look the same, but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point value is an integer in the range 0 to 0x10FFFF (about 1.1 million values, the [actual number assigned](https://www.unicode.org/versions/latest/#Summary) [https://www.unicode.org/versions/latest/#Summary] is less than that). In the standard and in this document, a code point is written using the notation U+265E to mean the character with value 0x265e (9,822 in decimal).

The Unicode standard contains a lot of tables listing characters and their corresponding code points:

```
0061      'a'; LATIN SMALL LETTER A
0062      'b'; LATIN SMALL LETTER B
0063      'c'; LATIN SMALL LETTER C
...
007B      '{'; LEFT CURLY BRACKET
...
2167      'VIII'; ROMAN NUMERAL EIGHT
2168      'IX'; ROMAN NUMERAL NINE
...
265E      '♞'; BLACK CHESS KNIGHT
265F      '♟'; BLACK CHESS PAWN
...
1F600     '😄'; GRINNING FACE
1F609     '😏'; WINKING FACE
...
```

Strictly, these definitions imply that it's meaningless to say 'this is character U+265E'. U+265E is a code point, which represents some particular character; in this case, it represents the character 'BLACK CHESS KNIGHT', '♞'. In informal contexts, this distinction between code points and characters will sometimes be forgotten.

A character is represented on a screen or on paper by a set of graphical elements that's called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn't need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal's font renderer.

## Encodings

To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 through `0x10FFFF` (1,114,111 decimal). This sequence of code points needs to be represented in memory as a set of **code units**, and **code units** are then mapped to 8-bit bytes. The rules for translating a Unicode string into a sequence of bytes are called a **character encoding**, or just an **encoding**.

The first encoding you might think of is using 32-bit integers as the code unit, and then using the CPU's representation of 32-bit integers. In this representation, the string "Python" might look like this:

P				y					t					h					o
0x50	00	00	00	79	00	00	00	74	00	00	00	68	00	00	00	6f	00		
0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17		

This representation is straightforward but using it presents a number of problems.

1. It's not portable; different processors order the bytes differently.
2. It's very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by `0x00` bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation. Increased RAM usage doesn't matter too much (desktop computers have gigabytes of RAM, and strings aren't usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.
3. It's not compatible with existing C functions such as `strlen()`, so a new family of wide string functions would need to be used.

Therefore this encoding isn't used very much, and people instead choose other encodings that are more efficient and convenient, such as UTF-8.

UTF-8 is one of the most commonly used encodings, and Python

often defaults to using it. UTF stands for “Unicode Transformation Format”, and the ‘8’ means that 8-bit values are used in the encoding. (There are also UTF-16 and UTF-32 encodings, but they are less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is  $< 128$ , it’s represented by the corresponding byte value.
2. If the code point is  $\geq 128$ , it’s turned into a sequence of two, three, or four bytes, where each byte of the sequence is between 128 and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a sequence of bytes that contains embedded zero bytes only where they represent the null character (U+0000). This means that UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can’t handle zero bytes for anything other than end-of-string markers.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of commonly used characters can be represented with one or two bytes.
5. If bytes are corrupted or lost, it’s possible to determine the start of the next UTF-8-encoded code point and resynchronize. It’s also unlikely that random 8-bit data will look like valid UTF-8.
6. UTF-8 is a byte oriented encoding. The encoding specifies that each character is represented by a specific sequence of one or more bytes. This avoids the byte-ordering issues that can occur with integer and word oriented encodings, like UTF-16 and UTF-32, where the sequence of bytes varies depending on the hardware on which the string was encoded.

## References

The [Unicode Consortium site](https://www.unicode.org) [https://www.unicode.org] has character charts, a glossary, and PDF versions of the Unicode specification. Be prepared for some difficult reading. [A chronology](https://) [https://

[www.unicode.org/history/](http://www.unicode.org/history/)] of the origin and development of Unicode is also available on the site.

On the Computerphile Youtube channel, Tom Scott briefly [discusses the history of Unicode and UTF-8](https://www.youtube.com/watch?v=MijmeoH9LT4) [https://www.youtube.com/watch?v=MijmeoH9LT4] (9 minutes 36 seconds).

To help understand the standard, Jukka Korpela has written [an introductory guide](https://jkorpela.fi/unicode/guide.html) [https://jkorpela.fi/unicode/guide.html] to reading the Unicode character tables.

## Python's Unicode Support

Now that you've learned the rudiments of Unicode, we can look at Python's Unicode features.

### The String Type

Since Python 3.0, the language's `str` type contains Unicode characters, meaning any string created using `"unicode rocks!"`, `'unicode rocks!'`, or the triple-quoted string syntax is stored as Unicode.

The default encoding for Python source code is UTF-8, so you can simply include a Unicode character in a string literal:

```
try:
    with open('/tmp/input.txt', 'r') as f:
        ...
```

```
except OSError:
    # 'File not found' error message.
    print("Fichier non trouvé")
```

Side note: Python 3 also supports using Unicode characters in identifiers:

```
répertoire = "/tmp/records.log"
with open(répertoire, "w") as f:
    f.write("test\n")
```

If you can't enter a particular character in your editor or want to keep the source code ASCII-only for some reason, you can also use escape sequences in string literals. (Depending on your system, you may see the actual capital-delta glyph instead of a u escape.)

```
>>> "\N{GREEK CAPITAL LETTER DELTA}" # Using the character name
'\u0394'
>>> "\u0394"                         # Using a 16-bit hex escape
'\u0394'
>>> "\U00000394"                     # Using a 32-bit hex escape
'\u0394'
```

In addition, one can create a string using the `decode()` method of `bytes`. This method takes an *encoding* argument, such as UTF-8, and optionally an *errors* argument.

The *errors* argument specifies the response when the input string can't be converted according to the encoding's rules. Legal values for this argument are `'strict'` (raise a `UnicodeDecodeError` exception), `'replace'` (use U+FFFD, REPLACEMENT CHARACTER), `'ignore'` (just leave the character out of the Unicode result), or `'backslashreplace'` (inserts a `\xNN` escape sequence). The following examples show the differences:

```
>>> b'\x80abc'.decode("utf-8", "strict")
Traceback (most recent call last):
...
UnicodeDecodeError: 'utf-8' codec can't decode byte 0x80:
    invalid start byte
```

```
>>> b'\x80abc'.decode("utf-8", "replace")
'\ufffdabc'
>>> b'\x80abc'.decode("utf-8", "backslashreplace")
'\\x80abc'
>>> b'\x80abc'.decode("utf-8", "ignore")
'abc'
```

Encodings are specified as strings containing the encoding's name. Python comes with roughly 100 different encodings; see the Python Library Reference at [Standard Encodings](#) for a list. Some encodings have multiple names; for example, 'latin-1', 'iso\_8859\_1' and '8859' are all synonyms for the same encoding.

One-character Unicode strings can also be created with the `chr()` built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in `ord()` function that takes a one-character Unicode string and returns the code point value:

```
>>> chr(57344)
'\ue000'
>>> ord('\ue000')
57344
```

## Converting to Bytes

The opposite method of `bytes.decode()` is `str.encode()`, which returns a **bytes** representation of the Unicode string, encoded in the requested *encoding*.

The *errors* parameter is the same as the parameter of the `decode()` method but supports a few more possible handlers. As well as 'strict', 'ignore', and 'replace' (which in this case inserts a question mark instead of the unencodable character), there is also 'xmlcharrefreplace' (inserts an XML character reference), 'backslashreplace' (inserts a `\uNNNN` escape sequence) and 'namereplace' (inserts a `\N{...}` escape sequence).

The following example shows the different results:

```

>>> u = chr(40960) + 'abcd' + chr(1972)
>>> u.encode('utf-8')
b'\xea\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
Traceback (most recent call last):
...
UnicodeEncodeError: 'ascii' codec can't encode character
  position 0: ordinal not in range(128)
>>> u.encode('ascii', 'ignore')
b'abcd'
>>> u.encode('ascii', 'replace')
b'?abcd?'
>>> u.encode('ascii', 'xmlcharrefreplace')
b'&#40960;abcd&#1972;'
>>> u.encode('ascii', 'backslashreplace')
b'\\ua000abcd\\u07b4'
>>> u.encode('ascii', 'namereplace')
b'\\N{YI SYLLABLE IT}abcd\\u07b4'

```

The low-level routines for registering and accessing the available encodings are found in the [codecs](#) module. Implementing new encodings also requires understanding the [codecs](#) module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, and writing new encodings is a specialized task, so the module won't be covered in this HOWTO.

## Unicode Literals in Python Source Code

In Python source code, specific Unicode code points can be written using the `\u` escape sequence, which is followed by four hex digits giving the code point. The `\U` escape sequence is similar, but expects eight hex digits, not four:

```

>>> s = "a\xac\u1234\u20ac\U00008000"
... #      ^^^^ two-digit hex escape
... #      ^^^^^ four-digit Unicode escape
... #      ^^^^^^^^^ eight-digit Unicode
>>> [ord(c) for c in s]

```

[97, 172, 4660, 8364, 32768]

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you're using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the `chr()` built-in function, but this is even more tedious.

Ideally, you'd want to be able to write literals in your language's natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing source code in UTF-8 by default, but you can use almost any encoding if you declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```
#!/usr/bin/env python
# -*- coding: latin-1 -*-

u = 'abcdé'
print(ord(u[-1]))
```

The syntax is inspired by Emacs's notation for specifying variables local to a file. Emacs supports many different variables, but Python only supports 'coding'. The `-*-` symbols indicate to Emacs that the comment is special; they have no significance to Python but are a convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don't include such a comment, the default encoding used will be UTF-8 as already mentioned. See also [PEP 263](https://peps.python.org/pep-0263/) [https://peps.python.org/pep-0263/] for more information.

## Unicode Properties

The Unicode specification includes a database of information about code points. For each defined code point, the information includes the character's name, its category, the numeric value if applicable

(for characters representing numeric concepts such as the Roman numerals, fractions such as one-third and four-fifths, etc.). There are also display-related properties, such as how to use the code point in bidirectional text.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```
import unicodedata

u = chr(233) + chr(0x0bf2) + chr(3972) + chr(6000) + chr(1000)

for i, c in enumerate(u):
    print(i, '%04x' % ord(c), unicodedata.category(c), end=' ')
    print(unicodedata.name(c))

# Get numeric value of second character
print(unicodedata.numeric(u[1]))
```

When run, this prints:

```
0 00e9 Ll LATIN SMALL LETTER E WITH ACUTE
1 0bf2 No TAMIL NUMBER ONE THOUSAND
2 0f84 Mn TIBETAN MARK HALANTA
3 1770 Lo TAGBANWA LETTER SA
4 33af So SQUARE RAD OVER S SQUARED
1000.0
```

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, 'Ll' means ‘Letter, lowercase’, 'No' means “Number, other”, 'Mn' is “Mark, nonspacing”, and 'So' is “Symbol, other”. See [the General Category Values section of the Unicode Character Database documentation](https://www.unicode.org/reports/tr44/#General_Category_Values) [https://www.unicode.org/reports/tr44/#General\_Category\_Values] for a list of category codes.

## Comparing Strings

Unicode adds some complication to comparing strings, because the same set of characters can be represented by different sequences of code points. For example, a letter like ‘ê’ can be represented as a single code point U+00EA, or as U+0065 U+0302, which is the code point for ‘e’ followed by a code point for ‘COMBINING CIRCUMFLEX ACCENT’. These will produce the same output when printed, but one is a string of length 1 and the other is of length 2.

One tool for a case-insensitive comparison is the `casefold()` string method that converts a string to a case-insensitive form following an algorithm described by the Unicode Standard. This algorithm has special handling for characters such as the German letter ‘ß’ (code point U+00DF), which becomes the pair of lowercase letters ‘ss’.

```
>>> street = 'Gürzenichstraße'
>>> street.casefold()
'gürzenichstrasse'
```

A second tool is the `unicodedata` module’s `normalize()` function that converts strings to one of several normal forms, where letters followed by a combining character are replaced with single characters. `normalize()` can be used to perform string comparisons that won’t falsely report inequality if two strings use combining characters differently:

```
import unicodedata

def compare_strs(s1, s2):
    def NFD(s):
        return unicodedata.normalize('NFD', s)

    return NFD(s1) == NFD(s2)

single_char = 'ê'
multiple_chars = '\N{LATIN SMALL LETTER E}\N{COMBINING CIRCUMFLEX ACCENT}'
print('length of first string=', len(single_char))
print('length of second string=', len(multiple_chars))
print(compare_strs(single_char, multiple_chars))
```

When run, this outputs:

```
$ python compare-strings.py
length of first string= 1
length of second string= 2
True
```

The first argument to the `normalize()` function is a string giving the desired normalization form, which can be one of 'NFC', 'NFKC', 'NFD', and 'NFKD'.

The Unicode Standard also specifies how to do caseless comparisons:

```
import unicodedata

def compare_caseless(s1, s2):
    def NFD(s):
        return unicodedata.normalize('NFD', s)

    return NFD(NFD(s1).casefold()) == NFD(NFD(s2).casefold())

# Example usage
single_char = 'ê'
multiple_chars = '\N{LATIN CAPITAL LETTER E}\N{COMBINING DIAERESIS}'

print(compare_caseless(single_char, multiple_chars))
```

This will print `True`. (Why is `NFD()` invoked twice? Because there are a few characters that make `casefold()` return a non-normalized string, so the result needs to be normalized again. See section 3.13 of the Unicode Standard for a discussion and an example.)

## Unicode Regular Expressions

The regular expressions supported by the `re` module can be provided either as bytes or strings. Some of the special character sequences such as `\d` and `\w` have different meanings depending on whether the pattern is supplied as bytes or a string. For example,

`\d` will match the characters `[0-9]` in bytes but in strings will match any character that's in the `'Nd'` category.

The string in this example has the number 57 written in both Thai and Arabic numerals:

```
import re
p = re.compile(r'\d+')

s = "Over \u0e55\u0e57 57 flavours"
m = p.search(s)
print(repr(m.group()))
```

When executed, `\d+` will match the Thai numerals and print them out. If you supply the `re.ASCII` flag to `compile()`, `\d+` will match the substring “57” instead.

Similarly, `\w` matches a wide variety of Unicode characters but only `[a-zA-Z0-9_]` in bytes or if `re.ASCII` is supplied, and `\s` will match either Unicode whitespace characters or `[\t\n\r\f\v]`.

EPC2002-Talk.pdf] at EuroPython 2002. The slides are an excellent overview of the design of Python 2's Unicode features (where the Unicode string type is called `unicode` and literals start with `u`).

## Reading and Writing Unicode Data

Once you've written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It's possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It's possible to do all the work yourself: open a file, read an 8-bit bytes object from it, and convert the bytes with `bytes.decode(encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1024 or 4096 bytes), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2 GiB file, you need 2 GiB of RAM. (More, really, since for at least a moment you'd need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch the case of partial coding sequences. The work of implementing this has already been done for you: the built-in `open()` function can return a file-like object that assumes the file's

contents are in a specified encoding and accepts Unicode parameters for methods such as `read()` and `write()`. This works through `open()`'s *encoding* and *errors* parameters which are interpreted just like those in `str.encode()` and `bytes.decode()`.

Reading Unicode from a file is therefore simple:

```
with open('unicode.txt', encoding='utf-8') as f:
    for line in f:
        print(repr(line))
```

It's also possible to open files in update mode, allowing both reading and writing:

```
with open('test', encoding='utf-8', mode='w+') as f:
    f.write('\u4500 blah blah blah\n')
    f.seek(0)
    print(repr(f.readline()[:1]))
```

The Unicode character `U+FEFF` is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file's byte ordering. Some encodings, such as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as 'utf-16-le' and 'utf-16-be' for little-endian and big-endian encodings, that specify one particular byte ordering and don't skip the BOM.

In some areas, it is also convention to use a "BOM" at the start of UTF-8 encoded files; the name is misleading since UTF-8 is not byte-order dependent. The mark simply announces that the file is encoded in UTF-8. For reading such files, use the 'utf-8-sig' codec to automatically skip the mark if present.

## Unicode filenames

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is

implemented by converting the Unicode string into some encoding that varies depending on the system. Today Python is converging on using UTF-8: Python on MacOS has used UTF-8 for several versions, and Python 3.6 switched to using UTF-8 on Windows as well. On Unix systems, there will only be a [filesystem encoding](#). if you've set the `LANG` or `LC_CTYPE` environment variables; if you haven't, the default encoding is again UTF-8.

The `sys.getfilesystemencoding()` function returns the encoding to use on your current system, in case you want to do the encoding manually, but there's not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```
filename = 'filename\u4500abc'
with open(filename, 'w') as f:
    f.write('blah\n')
```

Functions in the `os` module such as `os.stat()` will also accept Unicode filenames.

The `os.listdir()` function returns filenames, which raises an issue: should it return the Unicode version of filenames, or should it return bytes containing the encoded versions? `os.listdir()` can do both, depending on whether you provided the directory path as bytes or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing a byte path will return the filenames as bytes. For example, assuming the default [filesystem encoding](#) is UTF-8, running the following program:

```
fn = 'filename\u4500abc'
f = open(fn, 'w')
f.close()

import os
print(os.listdir(b'.'))
print(os.listdir('.'))
```

will produce the following output:

```
$ python listdir-test.py
[b'filename\xe4\x94\x80abc', ...]
['filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

Note that on most occasions, you should can just stick with using Unicode with these APIs. The bytes APIs should only be used on systems where undecodable file names can be present; that's pretty much only Unix systems now.

## Tips for Writing Unicode-aware Programs

This section provides some suggestions on writing software that deals with Unicode.

The most important tip is:

Software should only work with Unicode strings internally, decoding the input data as soon as possible and encoding the output only at the end.

If you attempt to write processing functions that accept both Unicode and byte strings, you will find your program vulnerable to bugs wherever you combine the two different kinds of strings. There is no automatic encoding or decoding: if you do e.g. `str + bytes`, a **`TypeError`** will be raised.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you're doing this, be careful to check the decoded string, not the encoded bytes data; some encodings may have interesting properties, such as not being bijective or not being fully ASCII-compatible. This is especially true if the input data also specifies the encoding, since the attacker can then choose a clever way to hide malicious text in the encoded bytestream.

## Converting Between File Encodings

The `StreamReader` class can transparently convert between encodings, taking a stream that returns data in encoding #1 and behaving like a stream returning data in encoding #2.

For example, if you have an input file *f* that's in Latin-1, you can wrap it with a `StreamReader` to return bytes encoded in UTF-8:

```
new_f = codecs.StreamReader(f,
    # en/decoder: used by read() to encode its results a
    # by write() to decode its input.
    codecs.getencoder('utf-8'), codecs.getdecoder('utf-8')

    # reader/writer: used to read and write to the stream
    codecs.getreader('latin-1'), codecs.getwriter('latin-1'))
```

## Files in an Unknown Encoding

What can you do if you need to make a change to a file, but don't know the file's encoding? If you know the encoding is ASCII-compatible and only want to examine or modify the ASCII parts, you can open the file with the `surrogateescape` error handler:

```
with open(fname, 'r', encoding="ascii", errors="surrogateescape") as f:
    data = f.read()

# make changes to the string 'data'

with open(fname + '.new', 'w',
    encoding="ascii", errors="surrogateescape") as f:
    f.write(data)
```

The `surrogateescape` error handler will decode any non-ASCII bytes as code points in a special range running from U+DC80 to U+DCFF. These code points will then turn back into the same bytes when the `surrogateescape` error handler is used to encode the data and write it back out.

# HOWTO Fetch Internet Resources Using The urllib Package

Author

[Michael Foord](https://agileabstractions.com/) [https://agileabstractions.com/]

## Introduction

### Related Articles

You may also find useful the following article on fetching web resources with Python:

- [Basic Authentication](https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml) [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml]

A tutorial on *Basic Authentication*, with examples in Python.

**urllib.request** is a Python module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the *urlopen* function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called handlers and openers.

**urllib.request** supports fetching URLs for many “URL schemes” (identified by the string before the “:” in URL - for example “ftp” is the URL scheme of “ftp://python.org/”) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations *urlopen* is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is [RFC 2616](https://datatracker.ietf.org/doc/html/rfc2616.html) [https://datatracker.ietf.org/doc/html/rfc2616.html]. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using *urllib*, with enough detail about HTTP to help you through. It is not intended to replace the [urllib.request](#) docs, but is supplementary to them.

## Fetching URLs

The simplest way to use `urllib.request` is as follows:

```
import urllib.request
with urllib.request.urlopen('http://python.org/') as res:
    html = response.read()
```

If you wish to retrieve a resource via URL and store it in a temporary location, you can do so via the [`shutil.copyfileobj\(\)`](#) and [`tempfile.NamedTemporaryFile\(\)`](#) functions:

```
import shutil
import tempfile
import urllib.request

with urllib.request.urlopen('http://python.org/') as res:
    with tempfile.NamedTemporaryFile(delete=False) as tmp_file:
        shutil.copyfileobj(response, tmp_file)

with open(tmp_file.name) as html:
    pass
```

Many uses of `urllib` will be that simple (note that instead of an ‘http:’ URL we could have used a URL starting with ‘ftp:’, ‘file:’, etc.). However, it’s the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests

and servers send responses. `urllib.request` mirrors this with a `Request` object which represents the HTTP request you are making. In its simplest form you create a `Request` object that specifies the URL you want to fetch. Calling `urlopen` with this `Request` object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```
import urllib.request

req = urllib.request.Request('http://python.org/')
with urllib.request.urlopen(req) as response:
    the_page = response.read()
```

Note that `urllib.request` makes use of the same `Request` interface to handle all URL schemes. For example, you can make an FTP request like so:

```
req = urllib.request.Request('ftp://example.com/')
```

In the case of HTTP, there are two extra things that `Request` objects allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information (“metadata”) *about* the data or about the request itself, to the server - this information is sent as HTTP “headers”. Let’s look at each of these in turn.

## Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script or other web application). With HTTP, this is often done using what’s known as a **POST** request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the `Request` object as the `data` argument. The encoding is done using a function from the `urllib.parse` library.

```
import urllib.parse
```

```
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python' }

data = urllib.parse.urlencode(values)
data = data.encode('ascii') # data should be bytes
req = urllib.request.Request(url, data)
with urllib.request.urlopen(req) as response:
    the_page = response.read()
```

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see [HTML Specification, Form Submission](https://www.w3.org/TR/REC-html40/interact/forms.html#h-17.13) [https://www.w3.org/TR/REC-html40/interact/forms.html#h-17.13] for more details).

If you do not pass the `data` argument, `urllib` uses a **GET** request. One way in which GET and POST requests differ is that POST requests often have “side-effects”: they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to *always* cause side-effects, and GET requests *never* to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```
>>> import urllib.request
>>> import urllib.parse
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
>>> url_values = urllib.parse.urlencode(data)
>>> print(url_values) # The order may differ from below
```

```
name=Somebody+Here&language=Python&location=Northampton
>>> url = 'http://www.example.com/example.cgi'
>>> full_url = url + '?' + url_values
>>> data = urllib.request.urlopen(full_url)
```

Notice that the full URL is created by adding a `?` to the URL, followed by the encoded values.

## Headers

We'll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [1](#) dislike being browsed by programs, or send different versions to different browsers [2](#). By default `urllib` identifies itself as `Python-urllib/x.y` (where `x` and `y` are the major and minor version numbers of the Python release, e.g. `Python-urllib/2.5`), which may confuse the site, or just plain not work. The way a browser identifies itself is through the `User-Agent` header [3](#). When you create a `Request` object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [4](#).

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/5.0 (Windows NT 6.1; Win64; x64)'
values = {'name': 'Michael Foord',
          'location': 'Northampton',
          'language': 'Python' }
headers = {'User-Agent': user_agent}

data = urllib.parse.urlencode(values)
data = data.encode('ascii')
req = urllib.request.Request(url, data, headers)
with urllib.request.urlopen(req) as response:
    the_page = response.read()
```

The response also has two useful methods. See the section on [info](#) and [geturl](#) which comes after we have a look at what happens when things go wrong.

## Handling Exceptions

*urlopen* raises **URLError** when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as **ValueError**, **TypeError** etc. may also be raised).

**HTTPError** is the subclass of **URLError** raised in the specific case of HTTP URLs.

The exception classes are exported from the **urllib.error** module.

### URLError

Often, **URLError** is raised because there is no network connection (no route to the specified server), or the specified server doesn't exist. In this case, the exception raised will have a 'reason' attribute, which is a tuple containing an error code and a text error message.

e.g.

```
>>> req = urllib.request.Request('http://www.pretend_server.com')
>>> try: urllib.request.urlopen(req)
... except urllib.error.URLError as e:
...     print(e.reason)
...
(4, 'getaddrinfo failed')
```

### HTTPError

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, **urllib** will handle that for you). For those it can't handle, *urlopen*

will raise an **HTTPError**. Typical errors include ‘404’ (page not found), ‘403’ (request forbidden), and ‘401’ (authentication required).

See section 10 of **RFC 2616** [<https://datatracker.ietf.org/doc/html/rfc2616.html>] for a reference on all the HTTP error codes.

The **HTTPError** instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

## Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100–299 range indicate success, you will usually only see error codes in the 400–599 range.

**http.server.BaseHTTPRequestHandler.responses** is a useful dictionary of response codes in that shows all the response codes used by **RFC 2616** [<https://datatracker.ietf.org/doc/html/rfc2616.html>]. The dictionary is reproduced here for convenience

```
# Table mapping response codes to messages; entries have
# form {code: (shortmessage, longmessage)}.
responses = {
    100: ('Continue', 'Request received, please continue'),
    101: ('Switching Protocols',
         'Switching to new protocol; obey Upgrade header'),

    200: ('OK', 'Request fulfilled, document follows'),
    201: ('Created', 'Document created, URL follows'),
    202: ('Accepted',
         'Request accepted, processing continues off-line'),
    203: ('Non-Authoritative Information', 'Request fulfilled from cache'),
    204: ('No Content', 'Request fulfilled, nothing follows'),
    205: ('Reset Content', 'Clear input form for further processing'),
    206: ('Partial Content', 'Partial content follows.'),

    300: ('Multiple Choices',
         'Object has several resources -- see URI list'),
    301: ('Moved Permanently', 'Object moved permanently -- see URI list'),
```

302: ('Found', 'Object moved temporarily -- see URI  
303: ('See Other', 'Object moved -- see Method and U  
304: ('Not Modified',  
      'Document has not changed since given time'),  
305: ('Use Proxy',  
      'You must use proxy specified in Location to a  
      'resource.'),  
307: ('Temporary Redirect',  
      'Object moved temporarily -- see URI list'),  
  
400: ('Bad Request',  
      'Bad request syntax or unsupported method'),  
401: ('Unauthorized',  
      'No permission -- see authorization schemes'),  
402: ('Payment Required',  
      'No payment -- see charging schemes'),  
403: ('Forbidden',  
      'Request forbidden -- authorization will not h  
404: ('Not Found', 'Nothing matches the given URI'),  
405: ('Method Not Allowed',  
      'Specified method is invalid for this server.'  
406: ('Not Acceptable', 'URI not available in prefer  
407: ('Proxy Authentication Required', 'You must aut  
      'this proxy before proceeding.'),  
408: ('Request Timeout', 'Request timed out; try aga  
409: ('Conflict', 'Request conflict.'),  
410: ('Gone',  
      'URI no longer exists and has been permanently  
411: ('Length Required', 'Client must specify Conten  
412: ('Precondition Failed', 'Precondition in header  
413: ('Request Entity Too Large', 'Entity is too lar  
414: ('Request-URI Too Long', 'URI is too long.'),  
415: ('Unsupported Media Type', 'Entity body in unsu  
416: ('Requested Range Not Satisfiable',  
      'Cannot satisfy request range.'),  
417: ('Expectation Failed',  
      'Expect condition could not be satisfied.'),

```

500: ('Internal Server Error', 'Server got itself in
501: ('Not Implemented',
      'Server does not support this operation'),
502: ('Bad Gateway', 'Invalid responses from another
503: ('Service Unavailable',
      'The server cannot process the request due to
504: ('Gateway Timeout',
      'The gateway server did not receive a timely r
505: ('HTTP Version Not Supported', 'Cannot fulfill
}

```

When an error is raised the server responds by returning an HTTP error code *and* an error page. You can use the [HTTPError](#) instance as a response on the page returned. This means that as well as the code attribute, it also has read, geturl, and info, methods as returned by the `urllib.response` module:

```

>>> req = urllib.request.Request('http://www.python.org/
>>> try:
...     urllib.request.urlopen(req)
... except urllib.error.HTTPError as e:
...     print(e.code)
...     print(e.read())
...
404
b'<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transiti
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.c
...
<title>Page Not Found</title>\n
...

```

## Wrapping it Up

So if you want to be prepared for [HTTPError](#) or [URLError](#) there are two basic approaches. I prefer the second approach.

### Number 1

```

from urllib.request import Request, urlopen

```

```

from urllib.error import URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError as e:
    print('The server couldn\'t fulfill the request.')
    print('Error code: ', e.code)
except URLError as e:
    print('We failed to reach a server.')
    print('Reason: ', e.reason)
else:
    # everything is fine

```

## Note

The `except HTTPError` *must* come first, otherwise `except URLError` will *also* catch an [HTTPError](#).

## Number 2

```

from urllib.request import Request, urlopen
from urllib.error import URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError as e:
    if hasattr(e, 'reason'):
        print('We failed to reach a server.')
        print('Reason: ', e.reason)
    elif hasattr(e, 'code'):
        print('The server couldn\'t fulfill the request.')
        print('Error code: ', e.code)
else:
    # everything is fine

```

## info and geturl

The response returned by `urlopen` (or the `HTTPError` instance) has two useful methods `info()` and `geturl()` and is defined in the module `urllib.response`.

**geturl** - this returns the real URL of the page fetched. This is useful because `urlopen` (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

**info** - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an `http.client.HTTPMessage` instance.

Typical headers include 'Content-length', 'Content-type', and so on. See the [Quick Reference to HTTP Headers](https://jkorpela.fi/http.html) [https://jkorpela.fi/http.html] for a useful listing of HTTP headers with brief explanations of their meaning and use.

## Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly named `urllib.request.OpenerDirector`). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a

quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an `opener` object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there's no need to call `install_opener`, except as a convenience.

## Basic Authentication

To illustrate creating and installing a handler we will use the `HTTPBasicAuthHandler`. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the [Basic Authentication Tutorial](https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml) [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml].

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a 'realm'. The header looks like: `WWW-Authenticate: SCHEME realm="REALM"`.

e.g.

```
WWW-Authenticate: Basic realm="cPanel Users"
```

The client should then retry the request with the appropriate name and password for the realm included as a header in the request. This is 'basic authentication'. In order to simplify this process we can create an instance of `HTTPBasicAuthHandler` and an opener to use this handler.

The `HTTPBasicAuthHandler` uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the

authentication header sent by the server), then you can use a `HTTPPasswordMgr`. Frequently one doesn't care what the realm is. In that case, it is convenient to use `HTTPPasswordMgrWithDefaultRealm`. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing `None` as the realm argument to the `add_password` method.

The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to `.add_password()` will also match.

```
# create a password manager
password_mgr = urllib.request.HTTPPasswordMgrWithDefaultRealm()

# Add the username and password.
# If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username, password)

handler = urllib.request.HTTPBasicAuthHandler(password_mgr)

# create "opener" (OpenerDirector instance)
opener = urllib.request.build_opener(handler)

# use the opener to fetch a URL
opener.open(a_url)

# Install the opener.
# Now all calls to urllib.request.urlopen use our opener
urllib.request.install_opener(opener)
```

## Note

In the above example we only supplied our `HTTPBasicAuthHandler` to `build_opener`. By default openers have the handlers for normal situations – `ProxyHandler` (if a proxy setting such as an `http_proxy`

environment variable is set), UnknownHandler, HTTPHandler, HTTPDefaultErrorHandler, HTTPRedirectHandler, FTPHandler, FileHandler, DataHandler, HTTPErrorProcessor.

`top_level_url` is in fact *either* a full URL (including the ‘http:’ scheme component and the hostname and optionally the port number) e.g. `"http://example.com/"` or an “authority” (i.e. the hostname, optionally including the port number) e.g. `"example.com"` or `"example.com:8080"` (the latter example includes a port number). The authority, if present, must NOT contain the “userinfo” component - for example `"joe:password@example.com"` is not correct.

## Proxies

`urllib` will auto-detect your proxy settings and use those. This is through the `ProxyHandler`, which is part of the normal handler chain when a proxy setting is detected. Normally that’s a good thing, but there are occasions when it may not be helpful [5](#). One way to do this is to setup our own `ProxyHandler`, with no proxies defined. This is done using similar steps to setting up a [Basic Authentication](https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml) [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml] handler:

```
>>> proxy_support = urllib.request.ProxyHandler({})
>>> opener = urllib.request.build_opener(proxy_support)
>>> urllib.request.install_opener(opener)
```

### Note

Currently `urllib.request` *does not* support fetching of `https` locations through a proxy. However, this can be enabled by extending `urllib.request` as shown in the recipe [6](#).

### Note

`HTTP_PROXY` will be ignored if a variable `REQUEST_METHOD` is

set; see the documentation on [getproxies\(\)](#).

## Sockets and Layers

The Python support for fetching resources from the web is layered. urllib uses the [http.client](#) library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has *no timeout* and can hang. Currently, the socket timeout is not exposed at the http.client or urllib.request levels. However, you can set the default timeout globally for all sockets using

```
import socket
import urllib.request

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib.request.urlopen now uses the default
# we have set in the socket module
req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
```

---

## Footnotes

This document was reviewed and revised by John Lee.

1

Google for example.

2

Browser sniffing is a very bad practice for website design - building sites using web standards is much more sensible.

Unfortunately a lot of sites still send different versions to different browsers.

3

The user agent for MSIE 6 is *'Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)'*

4

For details of more HTTP request headers, see [Quick Reference to HTTP Headers](https://jkorpela.fi/http.html) [https://jkorpela.fi/http.html].

5

In my case I have to use a proxy to access the internet at work. If you attempt to fetch *localhost* URLs through this proxy it blocks them. IE is set to use the proxy, which urllib picks up on. In order to test scripts with a localhost server, I have to prevent urllib from using the proxy.

# Argparse Tutorial

author

Tshepang Mbambo

This tutorial is intended to be a gentle introduction to [argparse](#), the recommended command-line parsing module in the Python standard library.

## Note

There are two other modules that fulfill the same task, namely [getopt](#) (an equivalent for `getopt()` from the C language) and the deprecated [optparse](#). Note also that [argparse](#) is based on [optparse](#), and therefore very similar in terms of usage.

## Concepts

Let's show the sort of functionality that we are going to explore in this introductory tutorial by making use of the `ls` command:

```
$ ls
cpython  devguide  prog.py  pypy  rm-unused-function.pat
$ ls pypy
ctypes_configure  demo  dotviewer  include  lib_pypy  li
$ ls -l
total 20
drwxr-xr-x 19 wena wena 4096 Feb 18 18:51 cpython
drwxr-xr-x  4 wena wena 4096 Feb  8 12:04 devguide
-rwxr-xr-x  1 wena wena  535 Feb 19 00:05 prog.py
drwxr-xr-x 14 wena wena 4096 Feb  7 00:59 pypy
-rw-r--r--  1 wena wena  741 Feb 18 01:01 rm-unused-func
$ ls --help
Usage: ls [OPTION]... [FILE]...
```

```
List information about the FILES (the current directory)
Sort entries alphabetically if none of -cftuvSUX nor --s
...
```

A few concepts we can learn from the four commands:

- The **ls** command is useful when run without any options at all. It defaults to displaying the contents of the current directory.
- If we want beyond what it provides by default, we tell it a bit more. In this case, we want it to display a different directory, `pypy`. What we did is specify what is known as a positional argument. It's named so because the program should know what to do with the value, solely based on where it appears on the command line. This concept is more relevant to a command like **cp**, whose most basic usage is `cp SRC DEST`. The first position is *what you want copied*, and the second position is *where you want it copied to*.
- Now, say we want to change behaviour of the program. In our example, we display more info for each file instead of just showing the file names. The `-l` in that case is known as an optional argument.
- That's a snippet of the help text. It's very useful in that you can come across a program you have never used before, and can figure out how it works simply by reading its help text.

## The basics

Let us start with a very simple example which does (almost) nothing:

```
import argparse
parser = argparse.ArgumentParser()
parser.parse_args()
```

Following is a result of running the code:

```
$ python prog.py
$ python prog.py --help
usage: prog.py [-h]
```

```
options:
  -h, --help  show this help message and exit
$ python prog.py --verbose
usage: prog.py [-h]
prog.py: error: unrecognized arguments: --verbose
$ python prog.py foo
usage: prog.py [-h]
prog.py: error: unrecognized arguments: foo
```

Here is what is happening:

- Running the script without any options results in nothing displayed to stdout. Not so useful.
- The second one starts to display the usefulness of the **argparse** module. We have done almost nothing, but already we get a nice help message.
- The `--help` option, which can also be shortened to `-h`, is the only option we get for free (i.e. no need to specify it). Specifying anything else results in an error. But even then, we do get a useful usage message, also for free.

## Introducing Positional arguments

An example:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo")
args = parser.parse_args()
print(args.echo)
```

And running the code:

```
$ python prog.py
usage: prog.py [-h] echo
prog.py: error: the following arguments are required: echo
$ python prog.py --help
usage: prog.py [-h] echo
```

```
positional arguments:
  echo
```

```
options:
```

```
-h, --help  show this help message and exit
$ python prog.py foo
foo
```

Here is what's happening:

- We've added the `add_argument()` method, which is what we use to specify which command-line options the program is willing to accept. In this case, I've named it `echo` so that it's in line with its function.
- Calling our program now requires us to specify an option.
- The `parse_args()` method actually returns some data from the options specified, in this case, `echo`.
- The variable is some form of 'magic' that `argparse` performs for free (i.e. no need to specify which variable that value is stored in). You will also notice that its name matches the string argument given to the method, `echo`.

Note however that, although the help display looks nice and all, it currently is not as helpful as it can be. For example we see that we got `echo` as a positional argument, but we don't know what it does, other than by guessing or by reading the source code. So, let's make it a bit more useful:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo", help="echo the string you use")
args = parser.parse_args()
print(args.echo)
```

And we get:

```
$ python prog.py -h
usage: prog.py [-h] echo
```

positional arguments:

```
echo          echo the string you use here
```

options:

```
-h, --help  show this help message and exit
```

Now, how about doing something even more useful:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square of")
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python prog.py 4
Traceback (most recent call last):
  File "prog.py", line 5, in <module>
    print(args.square**2)
TypeError: unsupported operand type(s) for ** or pow():
```

That didn't go so well. That's because **argparse** treats the options we give it as strings, unless we tell it otherwise. So, let's tell **argparse** to treat that input as an integer:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square of",
                    type=int)
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python prog.py 4
16
$ python prog.py four
usage: prog.py [-h] square
prog.py: error: argument square: invalid int value: 'four'
```

That went well. The program now even helpfully quits on bad illegal input before proceeding.

## Introducing Optional arguments

So far we have been playing with positional arguments. Let us have a look on how to add optional ones:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbosity", help="increase output")
args = parser.parse_args()
if args.verbosity:
    print("verbosity turned on")
```

And the output:

```
$ python prog.py --verbosity 1
verbosity turned on
$ python prog.py
$ python prog.py --help
usage: prog.py [-h] [--verbosity VERBOSITY]
```

options:

```
-h, --help            show this help message and exit
--verbosity VERBOSITY
                        increase output verbosity
```

```
$ python prog.py --verbosity
usage: prog.py [-h] [--verbosity VERBOSITY]
prog.py: error: argument --verbosity: expected one argument
```

Here is what is happening:

- The program is written so as to display something when `--verbosity` is specified and display nothing when not.
- To show that the option is actually optional, there is no error when running the program without it. Note that by default, if an optional argument isn't used, the relevant variable, in this case `args.verbosity`, is given `None` as a value, which is

the reason it fails the truth test of the `if` statement.

- The help message is a bit different.
- When using the `--verbosity` option, one must also specify some value, any value.

The above example accepts arbitrary integer values for `--verbosity`, but for our simple program, only two values are actually useful, `True` or `False`. Let's modify the code accordingly:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbose", help="increase output v
                    action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And the output:

```
$ python prog.py --verbose
verbosity turned on
$ python prog.py --verbose 1
usage: prog.py [-h] [--verbose]
prog.py: error: unrecognized arguments: 1
$ python prog.py --help
usage: prog.py [-h] [--verbose]
```

options:

```
-h, --help  show this help message and exit
--verbose  increase output verbosity
```

Here is what is happening:

- The option is now more of a flag than something that requires a value. We even changed the name of the option to match that idea. Note that we now specify a new keyword, `action`, and give it the value `"store_true"`. This means that, if the option is specified, assign the value `True` to `args.verbose`. Not specifying it implies `False`.
- It complains when you specify a value, in true spirit of what

flags actually are.

- Notice the different help text.

## Short options

If you are familiar with command line usage, you will notice that I haven't yet touched on the topic of short versions of the options. It's quite simple:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("-v", "--verbose", help="increase output
                    verbosity", action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And here goes:

```
$ python prog.py -v
verbosity turned on
$ python prog.py --help
usage: prog.py [-h] [-v]
```

options:

```
-h, --help            show this help message and exit
-v, --verbose         increase output verbosity
```

Note that the new ability is also reflected in the help text.

## Combining Positional and Optional arguments

Our program keeps growing in complexity:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given number")
```

```

parser.add_argument("-v", "--verbose", action="store_true",
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbose:
    print(f"the square of {args.square} equals {answer}")
else:
    print(answer)

```

And now the output:

```

$ python prog.py
usage: prog.py [-h] [-v] square
prog.py: error: the following arguments are required: square
$ python prog.py 4
16
$ python prog.py 4 --verbose
the square of 4 equals 16
$ python prog.py --verbose 4
the square of 4 equals 16

```

- We've brought back a positional argument, hence the complaint.
- Note that the order does not matter.

How about we give this program of ours back the ability to have multiple verbosity values, and actually get to use them:

```

import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given number")
parser.add_argument("-v", "--verbosity", type=int,
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print(f"the square of {args.square} equals {answer}")
elif args.verbosity == 1:
    print(f"{args.square}^2 == {answer}")

```

```
else:
    print(answer)
```

And the output:

```
$ python prog.py 4
16
$ python prog.py 4 -v
usage: prog.py [-h] [-v VERBOSITY] square
prog.py: error: argument -v/--verbosity: expected one ar
$ python prog.py 4 -v 1
4^2 == 16
$ python prog.py 4 -v 2
the square of 4 equals 16
$ python prog.py 4 -v 3
16
```

These all look good except the last one, which exposes a bug in our program. Let's fix it by restricting the values the `--verbosity` option can accept:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given nu
parser.add_argument("-v", "--verbosity", type=int, choice
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print(f"the square of {args.square} equals {answer}")
elif args.verbosity == 1:
    print(f"{args.square}^2 == {answer}")
else:
    print(answer)
```

And the output:

```
$ python prog.py 4 -v 3
usage: prog.py [-h] [-v {0,1,2}] square
```

```
prog.py: error: argument -v/--verbosity: invalid choice:
$ python prog.py 4 -h
usage: prog.py [-h] [-v {0,1,2}] square
```

positional arguments:

square	display a square of a given number
--------	------------------------------------

options:

-h, --help	show this help message and exit
-v {0,1,2}, --verbosity {0,1,2}	increase output verbosity

Note that the change also reflects both in the error message as well as the help string.

Now, let's use a different approach of playing with verbosity, which is pretty common. It also matches the way the CPython executable handles its own verbosity argument (check the output of `python --help`):

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display the square of a given number")
parser.add_argument("-v", "--verbosity", action="count",
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print(f"the square of {args.square} equals {answer}")
elif args.verbosity == 1:
    print(f"{args.square}^2 == {answer}")
else:
    print(answer)
```

We have introduced another action, “count”, to count the number of occurrences of specific options.

```
$ python prog.py 4
16
```

```
$ python prog.py 4 -v
4^2 == 16
$ python prog.py 4 -vv
the square of 4 equals 16
$ python prog.py 4 --verbosity --verbosity
the square of 4 equals 16
$ python prog.py 4 -v 1
usage: prog.py [-h] [-v] square
prog.py: error: unrecognized arguments: 1
$ python prog.py 4 -h
usage: prog.py [-h] [-v] square
```

positional arguments:

square	display a square of a given number
--------	------------------------------------

options:

-h, --help	show this help message and exit
-v, --verbosity	increase output verbosity

```
$ python prog.py 4 -vvv
16
```

- Yes, it's now more of a flag (similar to `action="store_true"`) in the previous version of our script. That should explain the complaint.
- It also behaves similar to “store\_true” action.
- Now here's a demonstration of what the “count” action gives. You've probably seen this sort of usage before.
- And if you don't specify the `-v` flag, that flag is considered to have `None` value.
- As should be expected, specifying the long form of the flag, we should get the same output.
- Sadly, our help output isn't very informative on the new ability our script has acquired, but that can always be fixed by improving the documentation for our script (e.g. via the `help` keyword argument).
- That last output exposes a bug in our program.

Let's fix:

```
import argparse
```

```

args = parser.parse_args()
answer = args.square**2
if args.verbosity >= 2:
    print(f"the square of {args.square} equals {answer}")
elif args.verbosity >= 1:
    print(f"{args.square}^2 == {answer}")
else:
    print(answer)

```

We've just introduced yet another keyword, `default`. We've set it to `0` in order to make it comparable to the other `int` values. Remember that by default, if an optional argument isn't specified, it gets the `None` value, and that cannot be compared to an `int` value (hence the `TypeError` exception).

And:

```

$ python prog.py 4
16

```

You can go quite far just with what we've learned so far, and we have only scratched the surface. The `argparse` module is very powerful, and we'll explore a bit more of it before we end this tutorial.

## Getting a little more advanced

What if we wanted to expand our tiny program to perform other powers, not just squares:

```

import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count",
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print(f"{args.x} to the power {args.y} equals {answer}")

```

```
elif args.verbosity >= 1:
    print(f"{args.x}^{args.y} == {answer}")
else:
    print(answer)
```

## Output:

```
$ python prog.py
usage: prog.py [-h] [-v] x y
prog.py: error: the following arguments are required: x,
$ python prog.py -h
usage: prog.py [-h] [-v] x y
```

positional arguments:

x	the base
y	the exponent

options:

-h, --help	show this help message and exit
-v, --verbosity	

```
$ python prog.py 4 2 -v
4^2 == 16
```

Notice that so far we've been using verbosity level to *change* the text that gets displayed. The following example instead uses verbosity level to display *more* text instead:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count",
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print(f"Running '{__file__}'")
if args.verbosity >= 1:
    print(f"{args.x}^{args.y} == ", end="")
print(answer)
```

Output:

```
$ python prog.py 4 2
16
$ python prog.py 4 2 -v
4^2 == 16
$ python prog.py 4 2 -vv
Running 'prog.py'
4^2 == 16
```

## Specifying ambiguous arguments

When there is ambiguity in deciding whether an argument is positional or for an argument, `--` can be used to tell `parse_args()` that everything after that is a positional argument:

```
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-n', nargs='+')
>>> parser.add_argument('args', nargs='*')

>>> # ambiguous, so parse_args assumes it's an option
>>> parser.parse_args(['-f'])
usage: PROG [-h] [-n N [N ...]] [args ...]
PROG: error: unrecognized arguments: -f

>>> parser.parse_args(['--', '-f'])
Namespace(args=['-f'], n=None)

>>> # ambiguous, so the -n option greedily accepts argument
>>> parser.parse_args(['-n', '1', '2', '3'])
Namespace(args=[], n=['1', '2', '3'])

>>> parser.parse_args(['-n', '1', '--', '2', '3'])
Namespace(args=['2', '3'], n=['1'])
```

## Conflicting options

So far, we have been working with two methods of an `argparse.ArgumentParser` instance. Let's introduce a third one,

`add_mutually_exclusive_group()`. It allows for us to specify options that conflict with each other. Let's also change the rest of the program so that the new functionality makes more sense: we'll introduce the `--quiet` option, which will be the opposite of the `--verbose` one:

```
import argparse

parser = argparse.ArgumentParser()
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print(f"{args.x} to the power {args.y} equals {answer}")
else:
    print(f"{args.x}^{args.y} == {answer}")
```

Our program is now simpler, and we've lost some functionality for the sake of demonstration. Anyways, here's the output:

```
$ python prog.py 4 2
4^2 == 16
$ python prog.py 4 2 -q
16
$ python prog.py 4 2 -v
4 to the power 2 equals 16
$ python prog.py 4 2 -vq
usage: prog.py [-h] [-v | -q] x y
prog.py: error: argument -q/--quiet: not allowed with -v
$ python prog.py 4 2 -v --quiet
usage: prog.py [-h] [-v | -q] x y
prog.py: error: argument -q/--quiet: not allowed with -v
```

That should be easy to follow. I've added that last output so you can see the sort of flexibility you get, i.e. mixing long form options with short form ones.

Before we conclude, you probably want to tell your users the main purpose of your program, just in case they don't know:

```
import argparse

parser = argparse.ArgumentParser(description="calculate
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print(f"{args.x} to the power {args.y} equals {answer}")
else:
    print(f"{args.x}^{args.y} == {answer}")
```

Note that slight difference in the usage text. Note the `[-v | -q]`, which tells us that we can either use `-v` or `-q`, but not both at the same time:

```
$ python prog.py --help
usage: prog.py [-h] [-v | -q] x y
```

calculate X to the power of Y

positional arguments:

x	the base
y	the exponent

options:

```
-h, --help      show this help message and exit
-v, --verbose
-q, --quiet
```

## How to translate the argparse output

The output of the [argparse](#) module such as its help text and error messages are all made translatable using the [gettext](#) module. This allows applications to easily localize messages produced by [argparse](#). See also [Internationalizing your programs and modules](#).

For instance, in this [argparse](#) output:

```
$ python prog.py --help
usage: prog.py [-h] [-v | -q] x y
```

```
calculate X to the power of Y
```

```
positional arguments:
```

```
  x                the base
  y                the exponent
```

```
options:
```

```
-h, --help      show this help message and exit
-v, --verbose
-q, --quiet
```

The strings `usage:`, `positional arguments:`, `options:` and `show this help message and exit` are all translatable.

In order to translate these strings, they must first be extracted into a `.po` file. For example, using [Babel](https://babel.pocoo.org/) [https://babel.pocoo.org/], run this command:

```
$ pybabel extract -o messages.po /usr/lib/python3.12/argparse
```

This command will extract all translatable strings from the [argparse](#) module and output them into a file named `messages.po`. This command assumes that your Python installation is in `/usr/lib`.

You can find out the location of the `argparse` module on your system using this script:

```
import argparse
print (argparse.__file__)
```

Once the messages in the `.po` file are translated and the translations are installed using `gettext`, `argparse` will be able to display the translated messages.

To translate your own strings in the `argparse` output, use `gettext`.

## Conclusion

The `argparse` module offers a lot more than shown here. Its docs are quite detailed and thorough, and full of examples. Having gone through this tutorial, you should easily digest them without feeling overwhelmed.

# An introduction to the `ipaddress` module

author

Peter Moody

author

Nick Coghlan

## Overview

This document aims to provide a gentle introduction to the `ipaddress` module. It is aimed primarily at users that aren't already familiar with IP networking terminology, but may also be useful to network engineers wanting an overview of how `ipaddress` represents IP network addressing concepts.

## Creating Address/Network/Interface objects

Since `ipaddress` is a module for inspecting and manipulating IP addresses, the first thing you'll want to do is create some objects. You can use `ipaddress` to create objects from strings and integers.

## A Note on IP Versions

For readers that aren't particularly familiar with IP addressing, it's important to know that the Internet Protocol (IP) is currently in the process of moving from version 4 of the protocol to version 6. This transition is occurring largely because version 4 of the protocol doesn't provide enough addresses to handle the needs of the whole world, especially given the increasing number of devices with direct connections to the internet.

Explaining the details of the differences between the two versions of the protocol is beyond the scope of this introduction, but readers need to at least be aware that these two versions exist, and it will sometimes be necessary to force the use of one version or the other.

## IP Host Addresses

Addresses, often referred to as “host addresses” are the most basic unit when working with IP addressing. The simplest way to create addresses is to use the `ipaddress.ip_address()` factory function, which automatically determines whether to create an IPv4 or IPv6 address based on the passed in value:

```
>>> ipaddress.ip_address('192.0.2.1')
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address('2001:DB8::1')
IPv6Address('2001:db8::1')
```

Addresses can also be created directly from integers. Values that will fit within 32 bits are assumed to be IPv4 addresses:

```
>>> ipaddress.ip_address(3221225985)
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address(4254076641128259285690398495165)
IPv6Address('2001:db8::1')
```

To force the use of IPv4 or IPv6 addresses, the relevant classes can be invoked directly. This is particularly useful to force creation of IPv6 addresses for small integers:

```
>>> ipaddress.ip_address(1)
IPv4Address('0.0.0.1')
>>> ipaddress.IPv4Address(1)
IPv4Address('0.0.0.1')
>>> ipaddress.IPv6Address(1)
IPv6Address('::1')
```

## Defining Networks

Host addresses are usually grouped together into IP networks, so

`ipaddress` provides a way to create, inspect and manipulate network definitions. IP network objects are constructed from strings that define the range of host addresses that are part of that network. The simplest form for that information is a “network address/network prefix” pair, where the prefix defines the number of leading bits that are compared to determine whether or not an address is part of the network and the network address defines the expected value of those bits.

As for addresses, a factory function is provided that determines the correct IP version automatically:

```
>>> ipaddress.ip_network('192.0.2.0/24')
IPv4Network('192.0.2.0/24')
>>> ipaddress.ip_network('2001:db8::0/96')
IPv6Network('2001:db8::/96')
```

Network objects cannot have any host bits set. The practical effect of this is that `192.0.2.1/24` does not describe a network. Such definitions are referred to as interface objects since the ip-on-a-network notation is commonly used to describe network interfaces of a computer on a given network and are described further in the next section.

By default, attempting to create a network object with host bits set will result in `ValueError` being raised. To request that the additional bits instead be coerced to zero, the flag `strict=False` can be passed to the constructor:

```
>>> ipaddress.ip_network('192.0.2.1/24')
Traceback (most recent call last):
...
ValueError: 192.0.2.1/24 has host bits set
>>> ipaddress.ip_network('192.0.2.1/24', strict=False)
IPv4Network('192.0.2.0/24')
```

While the string form offers significantly more flexibility, networks can also be defined with integers, just like host addresses. In this case, the network is considered to contain only the single address identified by the integer, so the network prefix includes the entire network address:

```
>>> ipaddress.ip_network(3221225984)
IPv4Network('192.0.2.0/32')
>>> ipaddress.ip_network(4254076641128259285690398495165)
IPv6Network('2001:db8::/128')
```

As with addresses, creation of a particular kind of network can be forced by calling the class constructor directly instead of using the factory function.

## Host Interfaces

As mentioned just above, if you need to describe an address on a particular network, neither the address nor the network classes are sufficient. Notation like `192.0.2.1/24` is commonly used by network engineers and the people who write tools for firewalls and routers as shorthand for “the host `192.0.2.1` on the network `192.0.2.0/24`”. Accordingly, `ipaddress` provides a set of hybrid classes that associate an address with a particular network. The interface for creation is identical to that for defining network objects, except that the address portion isn’t constrained to being a network address.

```
>>> ipaddress.ip_interface('192.0.2.1/24')
IPv4Interface('192.0.2.1/24')
>>> ipaddress.ip_interface('2001:db8::1/96')
IPv6Interface('2001:db8::1/96')
```

Integer inputs are accepted (as with networks), and use of a particular IP version can be forced by calling the relevant constructor directly.

## Inspecting Address/Network/Interface Objects

You’ve gone to the trouble of creating an `IPv(4|6)(Address|Network|Interface)` object, so you probably want to get information about it. `ipaddress` tries to make doing this easy and intuitive.

Extracting the IP version:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr6 = ipaddress.ip_address('2001:db8::1')
>>> addr6.version
6
>>> addr4.version
4
```

Obtaining the network from an interface:

```
>>> host4 = ipaddress.ip_interface('192.0.2.1/24')
>>> host4.network
IPv4Network('192.0.2.0/24')
>>> host6 = ipaddress.ip_interface('2001:db8::1/96')
>>> host6.network
IPv6Network('2001:db8::/96')
```

Finding out how many individual addresses are in a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.num_addresses
256
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.num_addresses
4294967296
```

Iterating through the “usable” addresses on a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> for x in net4.hosts():
...     print(x)
192.0.2.1
192.0.2.2
192.0.2.3
192.0.2.4
...
192.0.2.252
192.0.2.253
192.0.2.254
```

Obtaining the netmask (i.e. set bits corresponding to the network

prefix) or the hostmask (any bits that are not part of the netmask):

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.netmask
IPv4Address('255.255.255.0')
>>> net4.hostmask
IPv4Address('0.0.0.255')
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.netmask
IPv6Address('ffff:ffff:ffff:ffff:ffff:ffff::')
>>> net6.hostmask
IPv6Address('::ffff:ffff')
```

Exploding or compressing the address:

```
>>> addr6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0001'
>>> addr6.compressed
'2001:db8::1'
>>> net6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0000/96'
>>> net6.compressed
'2001:db8::/96'
```

While IPv4 doesn't support explosion or compression, the associated objects still provide the relevant properties so that version neutral code can easily ensure the most concise or most verbose form is used for IPv6 addresses while still correctly handling IPv4 addresses.

## Networks as lists of Addresses

It's sometimes useful to treat networks as lists. This means it is possible to index them like this:

```
>>> net4[1]
IPv4Address('192.0.2.1')
>>> net4[-1]
IPv4Address('192.0.2.255')
```

```
>>> net6[1]
IPv6Address('2001:db8::1')
>>> net6[-1]
IPv6Address('2001:db8::ffff:ffff')
```

It also means that network objects lend themselves to using the list membership test syntax like this:

```
if address in network:
    # do something
```

Containment testing is done efficiently based on the network prefix:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr4 in ipaddress.ip_network('192.0.2.0/24')
True
>>> addr4 in ipaddress.ip_network('192.0.3.0/24')
False
```

## Comparisons

**ipaddress** provides some simple, hopefully intuitive ways to compare objects, where it makes sense:

```
>>> ipaddress.ip_address('192.0.2.1') < ipaddress.ip_ad
True
```

A **TypeError** exception is raised if you try to compare objects of different versions or different types.

## Using IP Addresses with other modules

Other modules that use IP addresses (such as **socket**) usually won't accept objects from this module directly. Instead, they must be coerced to an integer or string that the other module will accept:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> str(addr4)
'192.0.2.1'
```

```
>>> int(addr4)
3221225985
```

## Getting more detail when instance creation fails

When creating address/network/interface objects using the version-agnostic factory functions, any errors will be reported as `ValueError` with a generic error message that simply says the passed in value was not recognized as an object of that type. The lack of a specific error is because it's necessary to know whether the value is *supposed* to be IPv4 or IPv6 in order to provide more detail on why it has been rejected.

To support use cases where it is useful to have access to this additional detail, the individual class constructors actually raise the `ValueError` subclasses `ipaddress.AddressValueError` and `ipaddress.NetmaskValueError` to indicate exactly which part of the definition failed to parse correctly.

The error messages are significantly more detailed when using the class constructors directly. For example:

```
>>> ipaddress.ip_address("192.168.0.256")
Traceback (most recent call last):
...
ValueError: '192.168.0.256' does not appear to be an IPv4 address
>>> ipaddress.IPv4Address("192.168.0.256")
Traceback (most recent call last):
...
ipaddress.AddressValueError: Octet 256 (> 255) not permitted

>>> ipaddress.ip_network("192.168.0.1/64")
Traceback (most recent call last):
...
ValueError: '192.168.0.1/64' does not appear to be an IPv4 network
>>> ipaddress.IPv4Network("192.168.0.1/64")
Traceback (most recent call last):
...
ipaddress.AddressValueError: Octet 256 (> 255) not permitted
```

```
ipaddress.NetmaskValueError: '64' is not a valid netmask
```

However, both of the module specific exceptions have `ValueError` as their parent class, so if you're not concerned with the particular type of error, you can still write code like the following:

```
try:
    network = ipaddress.IPv4Network(address)
except ValueError:
    print('address/netmask is invalid for IPv4:', address)
```

# Instrumenting CPython with DTrace and SystemTap

author

David Malcolm

author

Łukasz Langa

DTrace and SystemTap are monitoring tools, each providing a way to inspect what the processes on a computer system are doing. They both use domain-specific languages allowing a user to write scripts which:

- filter which processes are to be observed
- gather data from the processes of interest
- generate reports on the data

As of Python 3.6, CPython can be built with embedded “markers”, also known as “probes”, that can be observed by a DTrace or SystemTap script, making it easier to monitor what the CPython processes on a system are doing.

**CPython implementation detail:** DTrace markers are implementation details of the CPython interpreter. No guarantees are made about probe compatibility between versions of CPython. DTrace scripts can stop working or work incorrectly without warning when changing CPython versions.

## Enabling the static markers

macOS comes with built-in support for DTrace. On Linux, in order to build CPython with the embedded markers for SystemTap, the SystemTap development tools must be installed.

On a Linux machine, this can be done via:

```
$ yum install systemtap-sdt-devel
```

or:

```
$ sudo apt-get install systemtap-sdt-dev
```

CPython must then be **configured with the `--with-dtrace` option**:

```
checking for --with-dtrace... yes
```

On macOS, you can list available DTrace probes by running a Python process in the background and listing all probes made available by the Python provider:

```
$ python3.6 -q &
$ sudo dtrace -l -P python$! # or: dtrace -l -m python3
```

ID	PROVIDER	MODULE	
29564	python18035	python3.6	_PyEval_Eval
29565	python18035	python3.6	dtrace_fu
29566	python18035	python3.6	_PyEval_Eval
29567	python18035	python3.6	dtrace_fun
29568	python18035	python3.6	
29569	python18035	python3.6	
29570	python18035	python3.6	_PyEval_Eval
29571	python18035	python3.6	maybe

On Linux, you can verify if the SystemTap static markers are present in the built binary by seeing if it contains a “.note.stapsdt” section.

```
$ readelf -S ./python | grep .note.stapsdt
[30] .note.stapsdt          NOTE                0000000000000000
```

If you’ve built Python as a shared library (with the **`--enable-shared`** configure option), you need to look instead within the shared library. For example:

```
$ readelf -S libpython3.3dm.so.1.0 | grep .note.stapsdt
[29] .note.stapsdt          NOTE                0000000000000000
```

Sufficiently modern readelf can print the metadata:

```
$ readelf -n ./python
```

Displaying notes found at file offset 0x00000254 with length 0x00000010:

Arguments: 8@%rbp 8@%r12 -4@%eax		
stapsdt	0x00000046	NT_STAPSDT
Provider: python		
Name: function__return		
Location: 0x0000000000053dba8, Base: 0x0000000000000000		
Arguments: 8@%rbp 8@%r12 -4@%eax		

The above metadata contains information for SystemTap describing how it can patch strategically placed machine code instructions to

enable the tracing hooks used by a SystemTap script.

## Static DTrace probes

The following example DTrace script can be used to show the call/return hierarchy of a Python script, only tracing within the invocation of a function called “start”. In other words, import-time function invocations are not going to be listed:

```
self int indent;
```

```
python$target:::function-entry
/copyinstr(arg1) == "start"/
{
    self->trace = 1;
}
```

```
python$target:::function-entry
/self->trace/
{
    printf("%d\t%s:", timestamp, 15, probename);
    printf("%s", self->indent, "");
    printf("%s:%s:%d\n", basename(copyinstr(arg0)),
        self->indent++);
}
```

```
python$target:::function-return
/self->trace/
{
    self->indent--;
    printf("%d\t%s:", timestamp, 15, probename);
    printf("%s", self->indent, "");
    printf("%s:%s:%d\n", basename(copyinstr(arg0)),
        self->indent);
}
```

```
python$target:::function-return
/copyinstr(arg1) == "start"/
{
```

```
        self->trace = 0;
    }
```

It can be invoked like this:

```
$ sudo dtrace -q -s call_stack.d -c "python3.6 script.py"
```

The output looks like this:

```
156641360502280  function-entry:call_stack.py:start:23
156641360518804  function-entry: call_stack.py:function_
156641360532797  function-entry:  call_stack.py:function
156641360546807  function-return:  call_stack.py:function
156641360563367  function-return: call_stack.py:function_
156641360578365  function-entry: call_stack.py:function_
156641360591757  function-entry:  call_stack.py:function
156641360605556  function-entry:  call_stack.py:functio
156641360617482  function-return:  call_stack.py:functio
156641360629814  function-return: call_stack.py:function
156641360642285  function-return: call_stack.py:function_
156641360656770  function-entry: call_stack.py:function_
156641360669707  function-return: call_stack.py:function_
156641360687853  function-entry: call_stack.py:function_
156641360700719  function-return: call_stack.py:function_
156641360719640  function-entry: call_stack.py:function_
156641360732567  function-return: call_stack.py:function_
156641360747370  function-return:call_stack.py:start:28
```

## Static SystemTap markers

The low-level way to use the SystemTap integration is to use the static markers directly. This requires you to explicitly state the binary file containing them.

For example, this SystemTap script can be used to show the call/return hierarchy of a Python script:

```
probe process("python").mark("function__entry") {
    filename = user_string($arg1);
```

```

    funcname = user_string($arg2);
    lineno = $arg3;

    printf("%s => %s in %s:%d\\n",
           thread_indent(1), funcname, filename, lineno)
}

probe process("python").mark("function__return") {
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;

    printf("%s <= %s in %s:%d\\n",
           thread_indent(-1), funcname, filename, lineno)
}

```

It can be invoked like this:

```

$ stap \
  show-call-hierarchy.stp \
  -c "./python test.py"

```

The output looks like this:

```

11408 python(8274):          => __contains__ in Lib/_abcoll
11414 python(8274):          => __getitem__ in Lib/os.py:
11418 python(8274):          => encode in Lib/os.py:490
11424 python(8274):          <= encode in Lib/os.py:493
11428 python(8274):          <= __getitem__ in Lib/os.py:
11433 python(8274):          <= __contains__ in Lib/_abcoll

```

where the columns are:

- time in microseconds since start of script
- name of executable
- PID of process

and the remainder indicates the call/return hierarchy as the script executes.

For a `--enable-shared` build of CPython, the markers are contained within the libpython shared library, and the probe's dotted path needs to reflect this. For example, this line from the above example:

```
probe process("python").mark("function__entry") {
```

should instead read:

```
probe process("python").library("libpython3.6dm.so.1.0")
```

(assuming a `debug build` of CPython 3.6)

## Available static markers

`function_entry(str filename, str funcname, int lineno)`

This marker indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

The filename, function name, and line number are provided back to the tracing script as positional arguments, which must be accessed using `$arg1`, `$arg2`, `$arg3`:

- `$arg1`: (const char \*) filename, accessible using `user_string($arg1)`
- `$arg2`: (const char \*) function name, accessible using `user_string($arg2)`
- `$arg3`: int line number

`function_return(str filename, str funcname, int lineno)`

This marker is the converse of `function_entry()`, and indicates that execution of a Python function has ended (either via `return`, or via an exception). It is only triggered for pure-Python (bytecode) functions.

The arguments are the same as for `function_entry()`

`line(str filename, str funcname, int lineno)`

This marker indicates a Python line is about to be executed. It is the equivalent of line-by-line tracing with a Python profiler. It is not triggered within C functions.

The arguments are the same as for `function__entry()`.

`gc_start(int generation)`

Fires when the Python interpreter starts a garbage collection cycle. `arg0` is the generation to scan, like `gc.collect()`.

`gc_done(long collected)`

Fires when the Python interpreter finishes a garbage collection cycle. `arg0` is the number of collected objects.

`import_find_load_start(str modulename)`

Fires before `importlib` attempts to find and load the module. `arg0` is the module name.

*New in version 3.7.*

`import_find_load_done(str modulename, int found)`

Fires after `importlib`'s `find_and_load` function is called. `arg0` is the module name, `arg1` indicates if module was successfully loaded.

*New in version 3.7.*

`audit(str event, void *tuple)`

Fires when `sys.audit()` or `PySys_Audit()` is called. `arg0` is the event name as C string, `arg1` is a `PyObject` pointer to a tuple object.

*New in version 3.8.*

## SystemTap Tapsets

The higher-level way to use the SystemTap integration is to use a

“tapset”: SystemTap’s equivalent of a library, which hides some of the lower-level details of the static markers.

Here is a tapset file, based on a non-shared build of CPython:

```
/*
    Provide a higher-level wrapping around the function__
    function__return markers:
 */
probe python.function.entry = process("python").mark("fu
{
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;
    frameptr = $arg4
}
probe python.function.return = process("python").mark("f
{
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;
    frameptr = $arg4
}
```

If this file is installed in SystemTap’s tapset directory (e.g. `/usr/share/systemtap/tapset`), then these additional probepoints become available:

`python.function.entry(str filename, str funcname, int lineno, frameptr)`

This probe point indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

`python.function.return(str filename, str funcname, int lineno, frameptr)`

This probe point is the converse of `python.function.entry`, and indicates that execution of a Python function has ended (either via `return`, or via an

exception). It is only triggered for pure-Python (bytecode) functions.

## Examples

This SystemTap script uses the tapset above to more cleanly implement the example given above of tracing the Python function-call hierarchy, without needing to directly name the static markers:

```
probe python.function.entry
{
    printf("%s => %s in %s:%d\n",
           thread_indent(1), funcname, filename, lineno);
}

probe python.function.return
{
    printf("%s <= %s in %s:%d\n",
           thread_indent(-1), funcname, filename, lineno);
}
```

The following script uses the tapset above to provide a top-like view of all running CPython code, showing the top 20 most frequently entered bytecode frames, each second, across the whole system:

```
global fn_calls;

probe python.function.entry
{
    fn_calls[pid(), filename, funcname, lineno] += 1;
}

probe timer.ms(1000) {
    printf("\033[2J\033[1;1H") /* clear screen */
    printf("%6s %80s %6s %30s %6s\n",
           "PID", "FILENAME", "LINE", "FUNCTION", "CALLS");
    foreach ([pid, filename, funcname, lineno] in fn_calls)
        printf("%6d %80s %6d %30s %6d\n",
               pid, filename, lineno, funcname,
```

```
        fn_calls[pid, filename, funcname, lineno]);  
    }  
    delete fn_calls;  
}
```

# Python support for the Linux `perf` profiler

author

Pablo Galindo

[The Linux `perf` profiler](https://perf.wiki.kernel.org) [https://perf.wiki.kernel.org] is a very powerful tool that allows you to profile and obtain information about the performance of your application. `perf` also has a very vibrant ecosystem of tools that aid with the analysis of the data that it produces.

The main problem with using the `perf` profiler with Python applications is that `perf` only gets information about native symbols, that is, the names of functions and procedures written in C. This means that the names and file names of Python functions in your code will not appear in the output of `perf`.

Since Python 3.12, the interpreter can run in a special mode that allows Python functions to appear in the output of the `perf` profiler. When this mode is enabled, the interpreter will interpose a small piece of code compiled on the fly before the execution of every Python function and it will teach `perf` the relationship between this piece of code and the associated Python function using [perf map files](#).

## Note

Support for the `perf` profiler is currently only available for Linux on select architectures. Check the output of the `configure` build step or check the output of `python -m sysconfig | grep HAVE_PERF_TRAMPOLINE` to see if your system is supported.

For example, consider the following script:

```
def foo(n):
    result = 0
    for _ in range(n):
        result += 1
    return result

def bar(n):
    foo(n)

def baz(n):
    bar(n)

if __name__ == "__main__":
    baz(1000000)
```

We can run `perf` to sample CPU stack traces at 9999 hertz:

```
$ perf record -F 9999 -g -o perf.data python my_script.py
```

Then we can use `perf report` to analyze the data:

```
$ perf report --stdio -n -g
```

# Children	Self	Samples	Command	Shared O
# .....	.....	.....	.....	.....
#	91.08%	0.00%	0	python.exe python.e
	---_start			
		--90.71%--__libc_start_main		
		Py_BytesMain		
		--56.88%--pymain_run_python.com		
			--56.13%--_PyRun_Any	
			_PyRun_Sim	
				--55.02%--

[illegible]

Instead, if we run the same experiment with `perf` support enabled we get:

# Children	Self	Samples	Command	Shared C
# .....	.....	.....	.....	.....
#				
90.58%	0.36%	1	python.exe	python.e
	---_start			
	--89.86%--__libc_start_main			

## How to enable `perf` profiling support

`perf` profiling support can be enabled either from the start using the environment variable `PYTHONPERFSUPPORT` or the `-X perf` option, or dynamically using `sys.activate_stack_trampoline()` and `sys.deactivate_stack_trampoline()`.

The **sys** functions take precedence over the **-X** option, the **-X** option takes precedence over the environment variable.

Example, using the environment variable:

```
$ PYTHONPERFSUPPORT=1 python script.py
$ perf report -g -i perf.data
```

Example, using the **-X** option:

```
$ python -X perf script.py
$ perf report -g -i perf.data
```

Example, using the **sys** APIs in file `example.py`:

```
import sys

sys.activate_stack_trampoline("perf")
do_profiled_stuff()
sys.deactivate_stack_trampoline()

non_profiled_stuff()
```

...then:

```
$ python ./example.py
$ perf report -g -i perf.data
```

## How to obtain the best results

For best results, Python should be compiled with `CFLAGS="-fno-omit-frame-pointer -mno-omit-leaf-frame-pointer"` as this allows profilers to unwind using only the frame pointer and not on DWARF debug information. This is because as the code that is interposed to allow `perf` support is dynamically generated it doesn't have any DWARF debugging information available.

You can check if your system has been compiled with this flag by running:

```
$ python -m sysconfig | grep 'no-omit-frame-pointer'
```

If you don't see any output it means that your interpreter has not been compiled with frame pointers and therefore it may not be able to show Python functions in the output of `perf`.

# Annotations Best Practices

author

Larry Hastings

## Abstract

This document is designed to encapsulate the best practices for working with annotations dicts. If you write Python code that examines `__annotations__` on Python objects, we encourage you to follow the guidelines described below.

The document is organized into four sections: best practices for accessing the annotations of an object in Python versions 3.10 and newer, best practices for accessing the annotations of an object in Python versions 3.9 and older, other best practices for `__annotations__` that apply to any Python version, and quirks of `__annotations__`.

Note that this document is specifically about working with `__annotations__`, not uses *for* annotations. If you're looking for information on how to use "type hints" in your code, please see the [typing](#) module.

## Accessing The Annotations Dict Of An Object In Python 3.10 And Newer

Python 3.10 adds a new function to the standard library: `inspect.get_annotations()`. In Python versions 3.10 and newer, calling this function is the best practice for accessing the annotations dict of any object that supports annotations. This function can also "un-stringize" stringized annotations for you.

If for some reason `inspect.get_annotations()` isn't viable for

your use case, you may access the `__annotations__` data member manually. Best practice for this changed in Python 3.10 as well: as of Python 3.10, `o.__annotations__` is guaranteed to *always* work on Python functions, classes, and modules. If you're certain the object you're examining is one of these three *specific* objects, you may simply use `o.__annotations__` to get at the object's annotations dict.

However, other types of callables—for example, callables created by `functools.partial()`—may not have an `__annotations__` attribute defined. When accessing the `__annotations__` of a possibly unknown object, best practice in Python versions 3.10 and newer is to call `getattr()` with three arguments, for example `getattr(o, '__annotations__', None)`.

Before Python 3.10, accessing `__annotations__` on a class that defines no annotations but that has a parent class with annotations would return the parent's `__annotations__`. In Python 3.10 and newer, the child class's annotations will be an empty dict instead.

## Accessing The Annotations Dict Of An Object In Python 3.9 And Older

In Python 3.9 and older, accessing the annotations dict of an object is much more complicated than in newer versions. The problem is a design flaw in these older versions of Python, specifically to do with class annotations.

Best practice for accessing the annotations dict of other objects—functions, other callables, and modules—is the same as best practice for 3.10, assuming you aren't calling `inspect.get_annotations()`: you should use three-argument `getattr()` to access the object's `__annotations__` attribute.

Unfortunately, this isn't best practice for classes. The problem is that, since `__annotations__` is optional on classes, and because classes can inherit attributes from their base classes, accessing the `__annotations__` attribute of a class may inadvertently return the annotations dict of a *base class*. As an example:

```
class Base:
    a: int = 3
    b: str = 'abc'

class Derived(Base):
    pass

print(Derived.__annotations__)
```

This will print the annotations dict from `Base`, not `Derived`.

Your code will have to have a separate code path if the object you're examining is a class (`isinstance(o, type)`). In that case, best practice relies on an implementation detail of Python 3.9 and before: if a class has annotations defined, they are stored in the class's `__dict__` dictionary. Since the class may or may not have annotations defined, best practice is to call the `get` method on the class dict.

To put it all together, here is some sample code that safely accesses the `__annotations__` attribute on an arbitrary object in Python 3.9 and before:

```
if isinstance(o, type):
    ann = o.__dict__.get('__annotations__', None)
else:
    ann = getattr(o, '__annotations__', None)
```

After running this code, `ann` should be either a dictionary or `None`. You're encouraged to double-check the type of `ann` using `isinstance()` before further examination.

Note that some exotic or malformed type objects may not have a `__dict__` attribute, so for extra safety you may also wish to use `getattr()` to access `__dict__`.

## Manually Un-Stringizing Stringized Annotations

In situations where some annotations may be “stringized”, and you wish to evaluate those strings to produce the Python values they represent, it really is best to call `inspect.get_annotations()` to do this work for you.

If you’re using Python 3.9 or older, or if for some reason you can’t use `inspect.get_annotations()`, you’ll need to duplicate its logic. You’re encouraged to examine the implementation of `inspect.get_annotations()` in the current Python version and follow a similar approach.

In a nutshell, if you wish to evaluate a stringized annotation on an arbitrary object `o`:

- If `o` is a module, use `o.__dict__` as the `globals` when calling `eval()`.
- If `o` is a class, use `sys.modules[o.__module__].__dict__` as the `globals`, and `dict(vars(o))` as the `locals`, when calling `eval()`.
- If `o` is a wrapped callable using `functools.update_wrapper()`, `functools.wraps()`, or `functools.partial()`, iteratively unwrap it by accessing either `o.__wrapped__` or `o.func` as appropriate, until you have found the root unwrapped function.
- If `o` is a callable (but not a class), use `o.__globals__` as the `globals` when calling `eval()`.

However, not all string values used as annotations can be successfully turned into Python values by `eval()`. String values could theoretically contain any valid string, and in practice there are valid use cases for type hints that require annotating with string values that specifically *can’t* be evaluated. For example:

- **PEP 604** [<https://peps.python.org/pep-0604/>] union types using `|`, before support for this was added to Python 3.10.
- Definitions that aren’t needed at runtime, only imported when `typing.TYPE_CHECKING` is true.

If `eval()` attempts to evaluate such values, it will fail and raise an

exception. So, when designing a library API that works with annotations, it's recommended to only attempt to evaluate string values when explicitly requested to by the caller.

## Best Practices For `__annotations__` In Any Python Version

- You should avoid assigning to the `__annotations__` member of objects directly. Let Python manage setting `__annotations__`.
- If you do assign directly to the `__annotations__` member of an object, you should always set it to a `dict` object.
- If you directly access the `__annotations__` member of an object, you should ensure that it's a dictionary before attempting to examine its contents.
- You should avoid modifying `__annotations__` dicts.
- You should avoid deleting the `__annotations__` attribute of an object.

## `__annotations__` Quirks

In all versions of Python 3, function objects lazy-create an annotations dict if no annotations are defined on that object. You can delete the `__annotations__` attribute using `del fn.__annotations__`, but if you then access `fn.__annotations__` the object will create a new empty dict that it will store and return as its annotations. Deleting the annotations on a function before it has lazily created its annotations dict will throw an `AttributeError`; using `del fn.__annotations__` twice in a row is guaranteed to always throw an `AttributeError`.

Everything in the above paragraph also applies to class and module objects in Python 3.10 and newer.

In all versions of Python 3, you can set `__annotations__` on a function object to `None`. However, subsequently accessing the annotations on that object using `fn.__annotations__` will lazy-create an empty dictionary as per the first paragraph of this section.

This is *not* true of modules and classes, in any Python version; those objects permit setting `__annotations__` to any Python value, and will retain whatever value is set.

If Python stringizes your annotations for you (using `from __future__ import annotations`), and you specify a string as an annotation, the string will itself be quoted. In effect the annotation is quoted *twice*. For example:

```
from __future__ import annotations
def foo(a: "str"): pass

print(foo.__annotations__)
```

This prints `{'a': "'str'"}`. This shouldn't really be considered a “quirk”; it's mentioned here simply because it might be surprising.

# Isolating Extension Modules

## Abstract

Traditionally, state belonging to Python extension modules was kept in C `static` variables, which have process-wide scope. This document describes problems of such per-process state and shows a safer way: per-module state.

The document also describes how to switch to per-module state where possible. This transition involves allocating space for that state, potentially switching from static types to heap types, and—perhaps most importantly—accessing per-module state from code.

## Who should read this

This guide is written for maintainers of [C-API](#) extensions who would like to make that extension safer to use in applications where Python itself is used as a library.

## Background

An *interpreter* is the context in which Python code runs. It contains configuration (e.g. the import path) and runtime state (e.g. the set of imported modules).

Python supports running multiple interpreters in one process. There are two cases to think about—users may run interpreters:

- in sequence, with several `Py_InitializeEx()` / `Py_FinalizeEx()` cycles, and
- in parallel, managing “sub-interpreters” using `Py_NewInterpreter()` / `Py_EndInterpreter()`.

Both cases (and combinations of them) would be most useful when embedding Python within a library. Libraries generally shouldn't make assumptions about the application that uses them, which include assuming a process-wide “main Python interpreter”.

Historically, Python extension modules don't handle this use case well. Many extension modules (and even some stdlib modules) use *per-process* global state, because C `static` variables are extremely easy to use. Thus, data that should be specific to an interpreter ends up being shared between interpreters. Unless the extension developer is careful, it is very easy to introduce edge cases that lead to crashes when a module is loaded in more than one interpreter in the same process.

Unfortunately, *per-interpreter* state is not easy to achieve. Extension authors tend to not keep multiple interpreters in mind when developing, and it is currently cumbersome to test the behavior.

## Enter Per-Module State

Instead of focusing on per-interpreter state, Python's C API is evolving to better support the more granular *per-module* state. This means that C-level data should be attached to a *module object*. Each interpreter creates its own module object, keeping the data separate. For testing the isolation, multiple module objects corresponding to a single extension can even be loaded in a single interpreter.

Per-module state provides an easy way to think about lifetime and resource ownership: the extension module will initialize when a module object is created, and clean up when it's freed. In this regard, a module is just like any other [PyObject\\*](#); there are no “on interpreter shutdown” hooks to think—or forget—about.

Note that there are use cases for different kinds of “globals”: per-process, per-interpreter, per-thread or per-task state. With per-module state as the default, these are still possible, but you should treat them as exceptional cases: if you need them, you should give them additional care and testing. (Note that this guide does not cover them.)

## Isolated Module Objects

The key point to keep in mind when developing an extension module is that several module objects can be created from a single shared library. For example:

```
>>> import sys
>>> import binascii
>>> old_binascii = binascii
>>> del sys.modules['binascii']
>>> import binascii # create a new module object
>>> old_binascii == binascii
False
```

As a rule of thumb, the two modules should be completely independent. All objects and state specific to the module should be encapsulated within the module object, not shared with other module objects, and cleaned up when the module object is deallocated. Since this just is a rule of thumb, exceptions are possible (see [Managing Global State](#)), but they will need more thought and attention to edge cases.

While some modules could do with less stringent restrictions, isolated modules make it easier to set clear expectations and guidelines that work across a variety of use cases.

## Surprising Edge Cases

Note that isolated modules do create some surprising edge cases. Most notably, each module object will typically not share its classes and exceptions with other similar modules. Continuing from the [example above](#), note that `old_binascii.Error` and `binascii.Error` are separate objects. In the following code, the exception is *not* caught:

```
>>> old_binascii.Error == binascii.Error
False
>>> try:
...     old_binascii.unhexlify(b'qwertyuiop')
... except binascii.Error:
```

```
...     print('boo')
...
Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
binascii.Error: Non-hexadecimal digit found
```

This is expected. Notice that pure-Python modules behave the same way: it is a part of how Python works.

The goal is to make extension modules safe at the C level, not to make hacks behave intuitively. Mutating `sys.modules` “manually” counts as a hack.

## Making Modules Safe with Multiple Interpreters

### Managing Global State

Sometimes, the state associated with a Python module is not specific to that module, but to the entire process (or something else “more global” than a module). For example:

- The `readline` module manages *the* terminal.
- A module running on a circuit board wants to control *the* on-board LED.

In these cases, the Python module should provide *access* to the global state, rather than *own* it. If possible, write the module so that multiple copies of it can access the state independently (along with other libraries, whether for Python or other languages). If that is not possible, consider explicit locking.

If it is necessary to use process-global state, the simplest way to avoid issues with multiple interpreters is to explicitly prevent a module from being loaded more than once per process—see [Opt-Out: Limiting to One Module Object per Process](#).

### Managing Per-Module State

To use per-module state, use [multi-phase extension module initialization](#). This signals that your module supports multiple interpreters correctly.

Set `PyModuleDef.m_size` to a positive number to request that many bytes of storage local to the module. Usually, this will be set to the size of some module-specific `struct`, which can store all of the module's C-level state. In particular, it is where you should put pointers to classes (including exceptions, but excluding static types) and settings (e.g. `csv`'s [field\\_size\\_limit](#)) which the C code needs to function.

### Note

Another option is to store state in the module's `__dict__`, but you must avoid crashing when users modify `__dict__` from Python code. This usually means error- and type-checking at the C level, which is easy to get wrong and hard to test sufficiently.

However, if module state is not needed in C code, storing it in `__dict__` only is a good idea.

If the module state includes `PyObject` pointers, the module object must hold references to those objects and implement the module-level hooks `m_traverse`, `m_clear` and `m_free`. These work like `tp_traverse`, `tp_clear` and `tp_free` of a class. Adding them will require some work and make the code longer; this is the price for modules which can be unloaded cleanly.

An example of a module with per-module state is currently available as [xxlimited](#) [<https://github.com/python/cpython/blob/master/Modules/xxlimited.c>]; example module initialization shown at the bottom of the file.

## Opt-Out: Limiting to One Module Object per Process

A non-negative `PyModuleDef.m_size` signals that a module supports multiple interpreters correctly. If this is not yet the case for your module, you can explicitly make your module loadable only once per process. For example:

```
static int loaded = 0;

static int
exec_module(PyObject* module)
{
    if (loaded) {
        PyErr_SetString(PyExc_ImportError,
                        "cannot load module more than once")
        return -1;
    }
    loaded = 1;
    // ... rest of initialization
}
```

## Module State Access from Functions

Accessing the state from module-level functions is straightforward. Functions get the module object as their first argument; for extracting the state, you can use `PyModule_GetState`:

```
static PyObject *
func(PyObject *module, PyObject *args)
{
    my_struct *state = (my_struct*)PyModule_GetState(module);
    if (state == NULL) {
        return NULL;
    }
    // ... rest of logic
}
```

### Note

`PyModule_GetState` may return `NULL` without setting an exception if there is no module state, i.e.

`PyModuleDef.m_size` was zero. In your own module, you're in control of `m_size`, so this is easy to prevent.

## Heap Types

Traditionally, types defined in C code are *static*; that is, `static PyObject` structures defined directly in code and initialized using `PyType_Ready()`.

Such types are necessarily shared across the process. Sharing them between module objects requires paying attention to any state they own or access. To limit the possible issues, static types are immutable at the Python level: for example, you can't set `str.myattribute = 123`.

**CPython implementation detail:** Sharing truly immutable objects between interpreters is fine, as long as they don't provide access to mutable objects. However, in CPython, every Python object has a mutable implementation detail: the reference count. Changes to the `refcount` are guarded by the GIL. Thus, code that shares any Python objects across interpreters implicitly depends on CPython's current, process-wide GIL.

Because they are immutable and process-global, static types cannot access “their” module state. If any method of such a type requires access to module state, the type must be converted to a *heap-allocated type*, or *heap type* for short. These correspond more closely to classes created by Python's `class` statement.

For new modules, using heap types by default is a good rule of thumb.

## Changing Static Types to Heap Types

Static types can be converted to heap types, but note that the heap type API was not designed for “lossless” conversion from static types—that is, creating a type that works exactly like a given static type. So, when rewriting the class definition in a new API, you are likely to unintentionally change a few details (e.g. pickleability or inherited slots). Always test the details that are important to you.

Watch out for the following two points in particular (but note that this is not a comprehensive list):

- Unlike static types, heap type objects are mutable by default. Use the `Py_TPFLAGS_IMMUTABLETYPE` flag to prevent

mutability.

- Heap types inherit `tp_new` by default, so it may become possible to instantiate them from Python code. You can prevent this with the `Py_TPFLAGS_DISALLOW_INSTANTIATION` flag.

## Defining Heap Types

Heap types can be created by filling a `PyType_Spec` structure, a description or “blueprint” of a class, and calling `PyType_FromModuleAndSpec()` to construct a new class object.

### Note

Other functions, like `PyType_FromSpec()`, can also create heap types, but `PyType_FromModuleAndSpec()` associates the module with the class, allowing access to the module state from methods.

The class should generally be stored in *both* the module state (for safe access from C) and the module’s `__dict__` (for access from Python code).

## Garbage-Collection Protocol

Instances of heap types hold a reference to their type. This ensures that the type isn’t destroyed before all its instances are, but may result in reference cycles that need to be broken by the garbage collector.

To avoid memory leaks, instances of heap types must implement the garbage collection protocol. That is, heap types should:

- Have the `Py_TPFLAGS_HAVE_GC` flag.
- Define a traverse function using `Py_tp_traverse`, which visits the type (e.g. using `Py_VISIT(Py_TYPE(self))`).

Please refer to the [the documentation](#) of `Py_TPFLAGS_HAVE_GC` and `tp_traverse` for additional considerations.

If your traverse function delegates to the `tp_traverse` of its base class (or another type), ensure that `Py_TYPE(self)` is visited only once. Note that only heap type are expected to visit the type in `tp_traverse`.

For example, if your traverse function includes:

```
base->tp_traverse(self, visit, arg)
```

...and `base` may be a static type, then it should also include:

```
if (base->tp_flags & Py_TPFLAGS_HEAPTYPE) {
    // a heap type's tp_traverse already visited Py_TYPE
} else {
    Py_VISIT(Py_TYPE(self));
}
```

It is not necessary to handle the type's reference count in `tp_new` and `tp_clear`.

## Module State Access from Classes

If you have a type object defined with

`PyType_FromModuleAndSpec()`, you can call `PyType_GetModule()` to get the associated module, and then `PyModule_GetState()` to get the module's state.

To save a some tedious error-handling boilerplate code, you can combine these two steps with `PyType_GetModuleState()`, resulting in:

```
my_struct *state = (my_struct*)PyType_GetModuleState(type)
if (state == NULL) {
    return NULL;
}
```

## Module State Access from Regular Methods

Accessing the module-level state from methods of a class is somewhat more complicated, but is possible thanks to API

introduced in Python 3.9. To get the state, you need to first get the *defining class*, and then get the module state from it.

The largest roadblock is getting *the class a method was defined in*, or that method's “defining class” for short. The defining class can have a reference to the module it is part of.

Do not confuse the defining class with `Py_TYPE(self)`. If the method is called on a *subclass* of your type, `Py_TYPE(self)` will refer to that subclass, which may be defined in different module than yours.

## Note

The following Python code can illustrate the concept.

`Base.get_defining_class` returns `Base` even if `type(self) == Sub`:

```
class Base:
    def get_type_of_self(self):
        return type(self)

    def get_defining_class(self):
        return __class__

class Sub(Base):
    pass
```

For a method to get its “defining class”, it must use the [METH\\_METHOD](#) | [METH\\_FASTCALL](#) | [METH\\_KEYWORDS](#) **calling convention** and the corresponding `PyCMethod` signature:

```
PyObject *PyCMethod(
    PyObject *self,           // object the method was called on
    PyTypeObject *defining_class, // defining class
    PyObject *const *args,     // C array of argument pointers
    Py_ssize_t nargs,         // length of "args"
    PyObject *kwnames)        // NULL, or dict of keyword names
```

Once you have the defining class, call

`PyType_GetModuleState()` to get the state of its associated module.

For example:

```
static PyObject *
example_method(PyObject *self,
               PyTypeObject *defining_class,
               PyObject *const *args,
               Py_ssize_t nargs,
               PyObject *kwnames)
{
    my_struct *state = (my_struct*)PyType_GetModuleState(
        if (state == NULL) {
            return NULL;
        }
        ... // rest of logic
    }
```

```
PyDoc_STRVAR(example_method_doc, "...");
```

```
static PyMethodDef my_methods[] = {
    {"example_method",
     (PyCFunction) (void (*)(void)) example_method,
     METH_METHOD | METH_FASTCALL | METH_KEYWORDS,
     example_method_doc},
    {NULL},
}
```

## Module State Access from Slot Methods, Getters and Setters

### Note

This is new in Python 3.11.

Slot methods—the fast C equivalents for special methods, such as `nb_add` for `__add__` or `tp_new` for initialization—have a very

simple API that doesn't allow passing in the defining class, unlike with `PyCMethod`. The same goes for getters and setters defined with `PyGetSetDef`.

To access the module state in these cases, use the `PyType_GetModuleByDef()` function, and pass in the module definition. Once you have the module, call `PyModule_GetState()` to get the state:

```
PyObject *module = PyType_GetModuleByDef(Py_TYPE(self),
my_struct *state = (my_struct*)PyModule_GetState(module)
if (state == NULL) {
    return NULL;
}
```

`PyType_GetModuleByDef()` works by searching the [method resolution order](#) (i.e. all superclasses) for the first superclass that has a corresponding module.

### Note

In very exotic cases (inheritance chains spanning multiple modules created from the same definition),

`PyType_GetModuleByDef()` might not return the module of the true defining class. However, it will always return a module with the same definition, ensuring a compatible C memory layout.

## Lifetime of the Module State

When a module object is garbage-collected, its module state is freed. For each pointer to (a part of) the module state, you must hold a reference to the module object.

Usually this is not an issue, because types created with `PyType_FromModuleAndSpec()`, and their instances, hold a reference to the module. However, you must be careful in reference counting when you reference module state from other places, such as callbacks for external libraries.

# Open Issues

Several issues around per-module state and heap types are still open.

Discussions about improving the situation are best held on the [capi-sig mailing list](https://mail.python.org/mailman3/lists/capi-sig.python.org/) [https://mail.python.org/mailman3/lists/capi-sig.python.org/].

## Per-Class Scope

It is currently (as of Python 3.11) not possible to attach state to individual *types* without relying on CPython implementation details (which may change in the future—perhaps, ironically, to allow a proper solution for per-class scope).

## Lossless Conversion to Heap Types

The heap type API was not designed for “lossless” conversion from static types; that is, creating a type that works exactly like a given static type.

## General Information

### What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. It supports multiple programming paradigms beyond object-oriented programming, such as procedural and functional programming. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C + + . It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants including Linux and macOS, and on Windows.

To find out more, start with [The Python Tutorial](#). The [Beginner's Guide to Python](#) [<https://wiki.python.org/moin/BeginnersGuide>] links to other introductory tutorials and resources for learning Python.

### What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF's mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF's home page is at <https://www.python.org/psf/>.

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via [the PSF donation page](#)

[<https://www.python.org/psf/donations/>].

## Are there copyright restrictions on the use of Python?

You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it's OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See [the license page](https://docs.python.org/3/license.html) [<https://docs.python.org/3/license.html>] to find further explanations and the full text of the PSF License.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult [the Trademark Usage Policy](https://www.python.org/psf/trademarks/) [<https://www.python.org/psf/trademarks/>] for more information.

## Why was Python created in the first place?

Here's a *very* brief summary of what started it all, written by Guido van Rossum:

I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).

I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of

Modula-3 and read the Modula-3 report. Modula-3 is the origin of the syntax and semantics used for exceptions, and some other Python features.

I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn't easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.

In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the `Misc/HISTORY` file.

## What is Python good for?

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating differences between files), internet protocols (HTTP, FTP, SMTP,

XML-RPC, POP, IMAP), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for [The Python Standard Library](#) to get an idea of what's available. A wide variety of third-party extensions are also available. Consult [the Python Package Index](https://pypi.org) [https://pypi.org] to find packages of interest to you.

## How does the Python version numbering scheme work?

Python versions are numbered “A.B.C” or “A.B”:

- A is the major version number – it is only incremented for really major changes in the language.
- B is the minor version number – it is incremented for less earth-shattering changes.
- C is the micro version number – it is incremented for each bugfix release.

See [PEP 6](https://peps.python.org/pep-0006/) [https://peps.python.org/pep-0006/] for more information about bugfix releases.

Not all releases are bugfix releases. In the run-up to a new feature release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren't yet finalized; it's not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix:

- The suffix for an alpha version is “aN” for some small number N.
- The suffix for a beta version is “bN” for some small number N.
- The suffix for a release candidate version is “rcN” for some

small number  $N$ .

In other words, all versions labeled  $2.0aN$  precede the versions labeled  $2.0bN$ , which precede versions labeled  $2.0cN$ , and *those* precede 2.0.

You may also find version numbers with a “+” suffix, e.g. “2.2+”. These are unreleased versions, built directly from the CPython development repository. In practice, after a final minor release is made, the version is incremented to the next minor version, which becomes the “a0” version, e.g. “2.4a0”.

See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

## How do I obtain a copy of the Python source?

The latest Python source distribution is always available from python.org, at <https://www.python.org/downloads/>. The latest development sources can be obtained at <https://github.com/python/cpython/>.

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the [Getting Started section of the Python Developer’s Guide](#) [<https://devguide.python.org/setup/>] for more information on getting the source code and compiling it.

## How do I get documentation on Python?

The standard documentation for the current stable version of Python is available at <https://docs.python.org/3/>. PDF, plain text, and downloadable HTML versions are also available at <https://docs.python.org/3/download.html>.

The documentation is written in reStructuredText and processed by [the Sphinx documentation tool](#) [<https://www.sphinx-doc.org/>]. The

reStructuredText source for the documentation is part of the Python source distribution.

## I've never programmed before. Is there a Python tutorial?

There are numerous tutorials and books available. The standard documentation includes [The Python Tutorial](#).

Consult [the Beginner's Guide](#) [<https://wiki.python.org/moin/BeginnersGuide>] to find information for beginning Python programmers, including lists of tutorials.

## Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, *comp.lang.python*, and a mailing list, [python-list](#) [<https://mail.python.org/mailman/listinfo/python-list>]. The newsgroup and mailing list are gatewayed into each other – if you can read news it's unnecessary to subscribe to the mailing list. *comp.lang.python* is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in *comp.lang.python.announce*, a low-traffic moderated list that receives about five postings per day. It's available as [the python-announce mailing list](#) [<https://mail.python.org/mailman3/lists/python-announce-list.python.org/>].

More info about other mailing lists and newsgroups can be found at <https://www.python.org/community/lists/>.

## How do I get a beta test version of Python?

Alpha and beta releases are available from <https://www.python.org/downloads/>. All releases are announced on the *comp.lang.python* and *comp.lang.python.announce* newsgroups and on the Python home page at <https://www.python.org/>; an RSS feed of news is available.

You can also access the development version of Python through Git. See [The Python Developer's Guide](https://devguide.python.org/) [https://devguide.python.org/] for details.

## How do I submit bug reports and patches for Python?

To report a bug or submit a patch, use the issue tracker at <https://github.com/python/cpython/issues>.

For more information on how Python is developed, consult [the Python Developer's Guide](https://devguide.python.org/) [https://devguide.python.org/].

## Are there any published articles about Python that I can reference?

It's probably best to cite your favorite book about Python.

The [very first article](https://ir.cwi.nl/pub/18204) [https://ir.cwi.nl/pub/18204] about Python was written in 1991 and is now quite outdated.

Guido van Rossum and Jelke de Boer, “Interactively Testing Remote Servers Using the Python Programming Language”, CWI Quarterly, Volume 4, Issue 4 (December 1991), Amsterdam, pp 283–303.

## Are there any books on Python?

Yes, there are many, and more are being published. See the python.org wiki at <https://wiki.python.org/moin/PythonBooks> for a list.

You can also search online bookstores for “Python” and filter out the Monty Python references; or perhaps search for “Python” and “language”.

## Where in the world is [www.python.org](https://www.python.org) located?

The Python project's infrastructure is located all over the world and is managed by the Python Infrastructure Team. Details [here](https://) [https://

infra.psf.io].

## Why is it called Python?

When he began implementing Python, Guido van Rossum was also reading the published scripts from “[Monty Python’s Flying Circus](https://en.wikipedia.org/wiki/Monty_Python)” [https://en.wikipedia.org/wiki/Monty\_Python], a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.

## Do I have to like “Monty Python’s Flying Circus”?

No, but it helps. :)

## Python in the real world

### How stable is Python?

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. As of version 3.9, Python will have a new feature release every 12 months ([PEP 602](https://peps.python.org/pep-0602/) [https://peps.python.org/pep-0602/]).

The developers issue bugfix releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 3.5.3, 3.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it’s guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the [Python download page](https://www.python.org/downloads/) [https://www.python.org/downloads/]. There are two production-ready versions of Python: 2.x and 3.x. The recommended version is 3.x, which is supported by most widely used libraries. Although 2.x is still widely used, [it is not maintained anymore](https://peps.python.org/pep-0373/) [https://peps.python.org/pep-0373/].

### How many people are using Python?

There are probably millions of users, though it's difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it's available from many different sites and packaged with many Linux distributions, so download statistics don't tell the whole story either.

The comp.lang.python newsgroup is very active, but not all Python users post to the group or even read it.

## Have any significant projects been done in Python?

See <https://www.python.org/about/success> for a list of projects that use Python. Consulting the proceedings for [past Python conferences](https://www.python.org/community/workshops/) [https://www.python.org/community/workshops/] will reveal contributions from many different companies and organizations.

High-profile Python projects include [the Mailman mailing list manager](https://www.list.org) [https://www.list.org] and [the Zope application server](https://www.zope.dev) [https://www.zope.dev]. Several Linux distributions, most notably [Red Hat](https://www.redhat.com) [https://www.redhat.com], have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

## What new developments are expected for Python in the future?

See <https://peps.python.org/> for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled "Python X.Y Release Schedule", where X.Y is a version that hasn't been publicly released yet.

New development is discussed on [the python-dev mailing list](https://mail.python.org/mailman3/lists/python-dev.python.org/) [https://mail.python.org/mailman3/lists/python-dev.python.org/].

## Is it reasonable to propose incompatible changes to Python?

In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be frowned upon. Even if you can provide a conversion program, there's still the problem of updating all documentation; many books have been written about Python, and we don't want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. **PEP 5** [<https://peps.python.org/pep-0005/>] describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

## Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose problems, design consistent interfaces, and encapsulate data. While learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students' first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be

assigned programming projects very early in the course that *do* something. Assignments aren't restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students' reach.

Python's interactive interpreter enables students to test language features while they're programming. They can keep a window with the interpreter running while they enter their program's source in another window. If they can't remember the methods for a list, they can do something like this:

```
>>> L = []
>>> dir(L)
['__add__', '__class__', '__contains__', '__delattr__',
 '__dir__', '__doc__', '__eq__', '__format__', '__ge__',
 '__getattr__', '__getitem__', '__gt__', '__hash__',
 '__imul__', '__init__', '__iter__', '__le__', '__len__',
 '__mul__', '__ne__', '__new__', '__reduce__', '__reduce_',
 '__repr__', '__reversed__', '__rmul__', '__setattr__',
 '__sizeof__', '__str__', '__subclasshook__', 'append',
 'copy', 'count', 'extend', 'index', 'insert', 'pop', 're',
 'reverse', 'sort']
>>> [d for d in dir(L) if '__' not in d]
['append', 'clear', 'copy', 'count', 'extend', 'index',
'append(...)
    L.append(object) -> None -- append object to end

>>> L.append(1)
>>> L
[1]
```

With the interpreter, documentation is never far from the student as they are programming.

There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult [the Python wiki](https://wiki.python.org/moin/PythonEditors) [https://wiki.python.org/moin/PythonEditors] for a full list of Python editing environments.

If you want to discuss Python's use in education, you may be interested in joining [the edu-sig mailing list](https://www.python.org/community/sigs/current/edu-sig) [https://www.python.org/community/sigs/current/edu-sig].

    - Why do lambdas defined in a loop with different values all return the same result?
    - How do I share global variables across modules?
    - What are the “best practices” for using `import` in a module?
    - Why are default values shared between objects?
    - How can I pass optional or keyword parameters from one function to another?
    - What is the difference between arguments and parameters?
    - Why did changing list ‘y’ also change list ‘x’?
    - How do I write a function with output parameters (call by reference)?
    - How do you make a higher order function in

## Python?

- How do I copy an object in Python?
- How can I find the methods or attributes of an object?
- How can my code discover the name of an object?
- What's up with the comma operator's precedence?
- Is there an equivalent of C's "?:" ternary operator?
- Is it possible to write obfuscated one-liners in Python?
- What does the slash(/) in the parameter list of a function mean?

## ○ Numbers and strings

- How do I specify hexadecimal and octal integers?
- Why does `-22 // 10` return `-3`?
- How do I get int literal attribute instead of `SyntaxError`?
- How do I convert a string to a number?
- How do I convert a number to a string?
- How do I modify a string in place?
- How do I use strings to call functions/methods?
- Is there an equivalent to Perl's `chomp()` for removing trailing newlines from strings?
- Is there a `scanf()` or `sscanf()` equivalent?
- What does 'UnicodeDecodeError' or 'UnicodeEncodeError' error mean?
- Can I end a raw string with an odd number of backslashes?

## ○ Performance

- My program is too slow. How do I speed it up?
- What is the most efficient way to concatenate many strings together?

## ○ Sequences (Tuples/Lists)

- How do I convert between tuples and lists?
- What's a negative index?

- How do I iterate over a sequence in reverse order?
- How do you remove duplicates from a list?
- How do you remove multiple items from a list?
- How do you make an array in Python?
- How do I create a multidimensional list?
- How do I apply a method or function to a sequence of objects?
- Why does `a_tuple[i] += ['item']` raise an exception when the addition works?
- I want to do a complicated sort: can you do a Schwartzian Transform in Python?
- How can I sort one list by values from another list?

## ○ Objects

- What is a class?
- What is a method?
- What is `self`?
- How do I check if an object is an instance of a given class or of a subclass of it?
- What is delegation?
- How do I call a method defined in a base class from a derived class that extends it?
- How can I organize my code to make it easier to change the base class?
- How do I create static class data and static class methods?
- How can I overload constructors (or methods) in Python?
- I try to use `__spam` and I get an error about `_SomeClassName_spam`.
- My class defines `__del__` but it is not called when I delete the object.
- How do I get a list of all instances of a given class?
- Why does the result of `id()` appear to be not unique?
- When can I rely on identity tests with the `is` operator?
- How can a subclass control what data is

- stored in an immutable instance?
- How do I cache method calls?
- Modules
  - How do I create a .pyc file?
  - How do I find the current module name?
  - How can I have modules that mutually import each other?
  - `_import__('x.y.z')` returns <module 'x'>; how do I get z?
  - When I edit an imported module and reimport it, the changes don't show up. Why does this happen?

## General Questions

### Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

Several debuggers for Python are described below, and the built-in function `breakpoint()` allows you to drop into any of them.

The `pdb` module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is [documented in the Library Reference Manual](#). You can also write your own debugger by using the code for `pdb` as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as [Tools/scripts/idle3](#) [<https://github.com/python/cpython/blob/main/Tools/scripts/idle3>]), includes a graphical debugger.

PythonWin is a Python IDE that includes a GUI debugger based on `pdb`. The PythonWin debugger colors breakpoints and has quite a few cool features such as debugging non-PythonWin programs. PythonWin is available as part of [pywin32](#) [<https://github.com/mhammond/pywin32>] project and as a part of the [ActivePython](#) [<https://www.activestate.com/products/python/>] distribution.

**Eric** [<https://eric-ide.python-projects.org/>] is an IDE built on PyQt and the Scintilla editing component.

**trepan3k** [<https://github.com/rocky/python3-trepan/>] is a gdb-like debugger.

**Visual Studio Code** [<https://code.visualstudio.com/>] is an IDE with debugging tools that integrates with version-control software.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- **Wing IDE** [<https://wingware.com/>]
- **Komodo IDE** [<https://www.activestate.com/products/komodo-ide/>]
- **PyCharm** [<https://www.jetbrains.com/pycharm/>]

## Are there tools to help find bugs or perform static analysis?

Yes.

**Pylint** [<https://pylint.pycqa.org/en/latest/index.html>] and **Pyflakes** [<https://github.com/PyCQA/pyflakes>] do basic checking that will help you catch bugs sooner.

Static type checkers such as **Mypy** [<https://mypy-lang.org/>], **Pyre** [<https://pyre-check.org/>], and **Pytype** [<https://github.com/google/pytype>] can check type hints in Python source code.

## How can I create a stand-alone binary from a Python script?

You don't need the ability to compile Python to C code if all you want is a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as **Tools/freeze** [<https://github.com/python/cpython/tree/main/Tools/>]

freeze]. It converts Python byte code to C arrays; with a C compiler you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

The following packages can help with the creation of console and GUI executables:

- [Nuitka](https://nuitka.net/) [https://nuitka.net/] (Cross-platform)
- [PyInstaller](https://pyinstaller.org/) [https://pyinstaller.org/] (Cross-platform)
- [PyOxidizer](https://pyoxidizer.readthedocs.io/en/stable/) [https://pyoxidizer.readthedocs.io/en/stable/] (Cross-platform)
- [cx\\_Freeze](https://marcelotduarte.github.io/cx_Freeze/) [https://marcelotduarte.github.io/cx\_Freeze/] (Cross-platform)
- [py2app](https://github.com/ronaldoussoren/py2app) [https://github.com/ronaldoussoren/py2app] (macOS only)
- [py2exe](https://www.py2exe.org/) [https://www.py2exe.org/] (Windows only)

## Are there coding standards or a style guide for Python programs?

Yes. The coding style required for standard library modules is documented as [PEP 8](https://peps.python.org/pep-0008/) [https://peps.python.org/pep-0008/].

## Core Language

### Why am I getting an `UnboundLocalError` when the variable has a value?

It can be a surprise to get the `UnboundLocalError` in previously

working code when it is modified by adding an assignment statement somewhere in the body of a function.

This code:

```
>>> x = 10
>>> def bar():
...     print(x)
...
>>> bar()
10
```

works, but this code:

```
>>> x = 10
>>> def foo():
...     print(x)
...     x += 1
```

results in an **UnboundLocalError**:

```
>>> foo()
Traceback (most recent call last):
...
UnboundLocalError: local variable 'x' referenced before
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any similarly named variable in the outer scope. Since the last statement in `foo` assigns a new value to `x`, the compiler recognizes it as a local variable. Consequently when the earlier `print(x)` attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it global:

```
>>> x = 10
>>> def foobar():
...     global x
...     print(x)
...     x += 1
```

```
...
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```
>>> print(x)
11
```

You can do a similar thing in a nested scope using the **nonlocal** keyword:

```
>>> def foo():
...     x = 10
...     def bar():
...         nonlocal x
...         print(x)
...         x += 1
...     bar()
...     print(x)
...
>>> foo()
10
11
```

## What are the rules for local and global variables in Python?

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a value anywhere within the function's body, it's assumed to be a local unless explicitly declared as global.

Though a bit surprising at first, a moment's consideration explains this. On one hand, requiring **global** for assigned variables provides a bar against unintended side-effects. On the other hand, if **global** was required for all global references, you'd be using

`global` all the time. You'd have to declare as `global` every reference to a built-in function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

## Why do lambdas defined in a loop with different values all return the same result?

Assume you use a `for` loop to define a few different lambdas (or even plain functions), e.g.:

```
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda: x**2)
```

This gives you a list that contains 5 lambdas that calculate `x**2`. You might expect that, when called, they would return, respectively, 0, 1, 4, 9, and 16. However, when you actually try you will see that they all return 16:

```
>>> squares[2]()
16
>>> squares[4]()
16
```

This happens because `x` is not local to the lambdas, but is defined in the outer scope, and it is accessed when the lambda is called — not when it is defined. At the end of the loop, the value of `x` is 4, so all the functions now return `4**2`, i.e. 16. You can also verify this by changing the value of `x` and see how the results of the lambdas change:

```
>>> x = 8
>>> squares[2]()
64
```

In order to avoid this, you need to save the values in variables local to the lambdas, so that they don't rely on the value of the global `x`:

```
>>> squares = []
```

```
>>> for x in range(5):  
...     squares.append(lambda n=x: n**2)
```

Here, `n=x` creates a new variable `n` local to the lambda and computed when the lambda is defined so that it has the same value that `x` had at that point in the loop. This means that the value of `n` will be 0 in the first lambda, 1 in the second, 2 in the third, and so on. Therefore each lambda will now return the correct result:

```
>>> squares[2]()  
4  
>>> squares[4]()  
16
```

Note that this behaviour is not peculiar to lambdas, but applies to regular functions too.

## How do I share global variables across modules?

The canonical way to share information across modules within a single program is to create a special module (often called `config` or `cfg`). Just import the `config` module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

`config.py`:

```
x = 0    # Default value of the 'x' configuration setting
```

`mod.py`:

```
import config  
config.x = 1
```

`main.py`:

```
import config  
import mod  
print(config.x)
```

Note that using a module is also the basis for implementing the singleton design pattern, for the same reason.

## What are the “best practices” for using import in a module?

In general, don't use `from module_name import *`. Doing so clutters the importer's namespace, and makes it much harder for linters to detect undefined names.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It's good practice if you import modules in the following order:

1. standard library modules – e.g. `sys`, `os`, `argparse`, `re`
2. third-party library modules (anything installed in Python's site-packages directory) – e.g. `dateutil`, `requests`, `PIL`, `Image`
3. locally developed modules

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

Circular imports are fine where both modules use the “`import <module>`” form of import. They fail when the 2nd module wants to grab a name out of the first (“`from module import name`”) and the import is at the top level. That's because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the import is called, the first module will have finished initializing, and the second module can do its import.

It may also be necessary to move imports out of the top level of

code if some of the modules are platform-specific. In that case, it may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it's necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in `sys.modules`.

## Why are default values shared between objects?

This type of bug commonly bites neophyte programmers. Consider this function:

```
def foo(mydict={}): # Danger: shared reference to one dict
    ... compute something ...
    mydict[key] = value
    return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()` begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and `None`, are safe from change. Changes to mutable objects such

as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use `None` as the default value and inside the function, check if the parameter is `None` and create a new list/dictionary/whatever if it is. For example, don't write:

```
def foo(mydict={}):  
    ...
```

but:

```
def foo(mydict=None):  
    if mydict is None:  
        mydict = {} # create a new dict for local names
```

This feature can be useful. When you have a function that's time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called “memoizing”, and can be implemented like this:

```
# Callers can only provide two parameters and optionally  
def expensive(arg1, arg2, *, _cache={}):  
    if (arg1, arg2) in _cache:  
        return _cache[(arg1, arg2)]  
  
    # Calculate the value  
    result = ... expensive computation ...  
    _cache[(arg1, arg2)] = result # Store result  
    return result
```

You could use a global variable containing a dictionary instead of the default value; it's a matter of taste.

## How can I pass optional or keyword parameters from one function to another?

Collect the arguments using the `*` and `**` specifiers in the

function's parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then pass these arguments when calling another function by using `*` and `**`:

```
def f(x, *args, **kwargs):
    ...
    kwargs['width'] = '14.3c'
    ...
    g(x, *args, **kwargs)
```

## What is the difference between arguments and parameters?

**Parameters** are defined by the names that appear in a function definition, whereas **arguments** are the values actually passed to a function when calling it. Parameters define what **kind of arguments** a function can accept. For example, given the function definition:

```
def func(foo, bar=None, **kwargs):
    pass
```

*foo*, *bar* and *kwargs* are parameters of *func*. However, when calling *func*, for example:

```
func(42, bar=314, extra=somevar)
```

the values `42`, `314`, and `somevar` are arguments.

## Why did changing list 'y' also change list 'x'?

If you wrote code like:

```
>>> x = []
>>> y = x
>>> y.append(10)
>>> y
[10]
>>> x
[10]
```

you might be wondering why appending an element to `y` changed `x` too.

There are two factors that produce this result:

1. Variables are simply names that refer to objects. Doing `y = x` doesn't create a copy of the list – it creates a new variable `y` that refers to the same object `x` refers to. This means that there is only one object (the list), and both `x` and `y` refer to it.
2. Lists are [mutable](#), which means that you can change their content.

After the call to `append()`, the content of the mutable object has changed from `[]` to `[10]`. Since both the variables refer to the same object, using either name accesses the modified value `[10]`.

If we instead assign an immutable object to `x`:

```
>>> x = 5 # ints are immutable
>>> y = x
>>> x = x + 1 # 5 can't be mutated, we are creating a new object
>>> x
6
>>> y
5
```

we can see that in this case `x` and `y` are not equal anymore. This is because integers are [immutable](#), and when we do `x = x + 1` we are not mutating the int `5` by incrementing its value; instead, we are creating a new object (the int `6`) and assigning it to `x` (that is, changing which object `x` refers to). After this assignment we have two objects (the ints `6` and `5`) and two variables that refer to them (`x` now refers to `6` but `y` still refers to `5`).

Some operations (for example `y.append(10)` and `y.sort()`) mutate the object, whereas superficially similar operations (for example `y = y + [10]` and `sorted(y)`) create a new object. In general in Python (and in all cases in the standard library) a method that mutates an object will return `None` to help avoid getting the two types of operations confused. So if you mistakenly

write `y.sort()` thinking it will give you a sorted copy of `y`, you'll instead end up with `None`, which will likely cause your program to generate an easily diagnosed error.

However, there is one class of operations where the same operation sometimes has different behaviors with different types: the augmented assignment operators. For example, `+=` mutates lists but not tuples or ints (`a_list += [1, 2, 3]` is equivalent to `a_list.extend([1, 2, 3])` and mutates `a_list`, whereas `some_tuple += (1, 2, 3)` and `some_int += 1` create new objects).

In other words:

- If we have a mutable object (**list**, **dict**, **set**, etc.), we can use some specific operations to mutate it and all the variables that refer to it will see the change.
- If we have an immutable object (**str**, **int**, **tuple**, etc.), all the variables that refer to it will always see the same value, but operations that transform that value into a new value always return a new object.

If you want to know if two variables refer to the same object or not, you can use the **is** operator, or the built-in function **id()**.

## How do I write a function with output parameters (call by reference)?

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

### 1. By returning a tuple of the results:

```
>>> def func1(a, b):  
...     a = 'new-value'           # a and b are local  
...     b = b + 1                 # assigned to new ob  
...     return a, b              # return new values
```

```
...
>>> x, y = 'old-value', 99
>>> func1(x, y)
('new-value', 100)
```

This is almost always the clearest solution.

2. By using global variables. This isn't thread-safe, and is not recommended.

3. By passing a mutable (changeable in-place) object:

```
>>> def func2(a):
...     a[0] = 'new-value'          # 'a' references a mutable object
...     a[1] = a[1] + 1             # changes a shared object in-place
...
>>> args = ['old-value', 99]
>>> func2(args)
>>> args
['new-value', 100]
```

4. By passing in a dictionary that gets mutated:

```
>>> def func3(args):
...     args['a'] = 'new-value'      # args is a mutable object
...     args['b'] = args['b'] + 1    # change it in-place
...
>>> args = {'a': 'old-value', 'b': 99}
>>> func3(args)
>>> args
{'a': 'new-value', 'b': 100}
```

5. Or bundle up values in a class instance:

```
>>> class Namespace:
...     def __init__(self, /, **args):
...         for key, value in args.items():
...             setattr(self, key, value)
...
>>> def func4(args):
```

```

...     args.a = 'new-value'           # args is a mut
...     args.b = args.b + 1           # change object
...
>>> args = Namespace(a='old-value', b=99)
>>> func4(args)
>>> vars(args)
{'a': 'new-value', 'b': 100}

```

There's almost never a good reason to get this complicated.

Your best choice is to return a tuple containing the multiple results.

## How do you make a higher order function in Python?

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define `linear(a,b)` which returns a function `f(x)` that computes the value `a*x+b`. Using nested scopes:

```

def linear(a, b):
    def result(x):
        return a * x + b
    return result

```

Or using a callable object:

```

class linear:
    def __init__(self, a, b):
        self.a, self.b = a, b

    def __call__(self, x):
        return self.a * x + self.b

```

In both cases,

```
taxes = linear(0.3, 2)
```

gives a callable object where `taxes(10e6) == 0.3 * 10e6 + 2`.

The callable object approach has the disadvantage that it is a bit slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:

```
class exponential(linear):
    # __init__ inherited
    def __call__(self, x):
        return self.a * (x ** self.b)
```

Object can encapsulate state for several methods:

```
class counter:

    value = 0

    def set(self, x):
        self.value = x

    def up(self):
        self.value = self.value + 1

    def down(self):
        self.value = self.value - 1

count = counter()
inc, dec, reset = count.up, count.down, count.set
```

Here `inc()`, `dec()` and `reset()` act like functions which share the same counting variable.

## How do I copy an object in Python?

In general, try `copy.copy()` or `copy.deepcopy()` for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a `copy()` method:

```
newdict = olddict.copy()
```

Sequences can be copied by slicing:

```
new_l = l[:]
```

## How can I find the methods or attributes of an object?

For an instance `x` of a user-defined class, `dir(x)` returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

## How can my code discover the name of an object?

Generally speaking, it can't, because objects don't really have names. Essentially, assignment always binds a name to a value; the same is true of `def` and `class` statements, but in that case the value is a callable. Consider the following code:

```
>>> class A:
...     pass
...
>>> B = A
>>> a = B()
>>> b = a
>>> print(b)
<__main__.A object at 0x16D07CC>
>>> print(a)
<__main__.A object at 0x16D07CC>
```

Arguably the class has a name: even though it is bound to two names and invoked through the name `B` the created instance is still reported as an instance of class `A`. However, it is impossible to say whether the instance's name is `a` or `b`, since both names are bound to the same value.

Generally speaking it should not be necessary for your code to “know the names” of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In `comp.lang.python`, Fredrik Lundh once gave an excellent analogy

in answer to this question:

The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn't really care – so the only way to find out what it's called is to ask all your neighbours (namespaces) if it's their cat (object)...

....and don't be surprised if you'll find that it's known by many names, or no name at all!

## What's up with the comma operator's precedence?

Comma is not an operator in Python. Consider this session:

```
>>> "a" in "b", "a"  
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:

```
("a" in "b"), "a"
```

not:

```
"a" in ("b", "a")
```

The same is true of the various assignment operators (=, += etc). They are not truly operators but syntactic delimiters in assignment statements.

## Is there an equivalent of C's “?:” ternary operator?

Yes, there is. The syntax is as follows:

```
[on_true] if [expression] else [on_false]
```

```
x, y = 50, 25  
small = x if x < y else y
```

Before this syntax was introduced in Python 2.5, a common idiom was to use logical operators:

```
[expression] and [on_true] or [on_false]
```

However, this idiom is unsafe, as it can give wrong results when *on\_true* has a false boolean value. Therefore, it is always better to use the ... if ... else ... form.

## Is it possible to write obfuscated one-liners in Python?

Yes. Usually this is done by nesting **lambda** within **lambda**. See the following three examples, slightly adapted from Ulf Bartelt:

```
from functools import reduce
```

```
# Primes < 1000
```

```
print(list(filter(None,map(lambda y:y*reduce(lambda x,y:
map(lambda x,y=y:y%x,range(2,int(pow(y,0.5)+1))),1),rang
```

```
# First 10 Fibonacci numbers
```

```
print(list(map(lambda x,f=lambda x,f:(f(x-1,f)+f(x-2,f))
f(x,f), range(10))))
```

```
# Mandelbrot set
```

```
print((lambda Ru,Ro,Iu,Io,IM,Sx,Sy:reduce(lambda x,y:x+
Iu=Iu,Io=Io,Ru=Ru,Ro=Ro,Sy=Sy,L=lambda yc,Iu=Iu,Io=Io,Ru=
Sx=Sx,Sy=Sy:reduce(lambda x,y:x+y,map(lambda x,xc=Ru,yc=
i=i,Sx=Sx,F=lambda xc,yc,x,y,k,f=lambda xc,yc,x,y,k,f:(k
>=4.0) or 1+f(xc,yc,x*x-y*y+xc,2.0*x*y+yc,k-1,f):f(xc,yc
64+F(Ru+x*(Ro-Ru)/Sx,yc,0,0,i)),range(Sx)):L(Iu+y*(Io-I
)))(-2.1, 0.7, -1.2, 1.2, 30, 80, 24))
```

```
#      \___ ___/   \___ ___/   |   |   |___ lines on screen
#          V          V          |   |___ columns on screen
#          |          |          |___ maximum of "itera
#          |          |___ range on y axis
#          |___ range on x axis
```

Don't try this at home, kids!

## What does the slash(/) in the parameter list of a function mean?

A slash in the argument list of a function denotes that the parameters prior to it are positional-only. Positional-only parameters are the ones without an externally usable name. Upon calling a function that accepts positional-only parameters, arguments are mapped to parameters based solely on their position. For example, `divmod()` is a function that accepts positional-only parameters. Its documentation looks like this:

```
>>> help(divmod)
Help on built-in function divmod in module builtins:

divmod(x, y, /)
    Return the tuple (x//y, x%y).  Invariant: div*y + mo
```

The slash at the end of the parameter list means that both parameters are positional-only. Thus, calling `divmod()` with keyword arguments would lead to an error:

```
>>> divmod(x=3, y=4)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: divmod() takes no keyword arguments
```

## Numbers and strings

### How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”. Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```
>>> a = 0xa5
>>> a
165
>>> b = 0XB2
>>> b
178
```

## Why does `-22 // 10` return `-3`?

It’s primarily driven by the desire that `i % j` have the same sign as `j`. If you want that, and also want:

```
i == (i // j) * j + (i % j)
```

then integer division has to return the floor. C also requires that identity to hold, and then compilers that truncate `i // j` need to make `i % j` have the same sign as `i`.

There are few real use cases for `i % j` when `j` is negative. When `j` is positive, there are many, and in virtually all of them it’s more useful for `i % j` to be  $\geq 0$ . If the clock says 10 now, what did it say 200 hours ago? `-190 % 12 == 2` is useful; `-190 % 12 == -10` is a bug waiting to bite.

## How do I get `int` literal attribute instead of `SyntaxError`?

Trying to lookup an `int` literal attribute in the normal manner gives a `SyntaxError` because the period is seen as a decimal point:

```
>>> 1.__class__
File "<stdin>", line 1
1.__class__
  ^
```

SyntaxError: invalid decimal literal

The solution is to separate the literal from the period with either a space or parentheses.

```
>>> 1.__class__  
<class 'int'>  
>>> (1).__class__  
<class 'int'>
```

## How do I convert a string to a number?

For integers, use the built-in `int()` type constructor, e.g. `int('144') == 144`. Similarly, `float()` converts to floating-point, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` holds true, and `int('0x144')` raises `ValueError`. `int(string, base)` takes the base to convert from as a second optional argument, so `int('0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python's rules: a leading '0o' indicates octal, and '0x' indicates a hex number.

Do not use the built-in function `eval()` if all you need is to convert strings to numbers. `eval()` will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because Python does not allow leading '0' in a decimal number (except '0').

## How do I convert a number to a string?

To convert, e.g., the number `144` to the string `'144'`, use the built-in type constructor `str()`. If you want a hexadecimal or octal representation, use the built-in functions `hex()` or `oct()`. For

fancy formatting, see the [Formatted string literals](#) and [Format String Syntax](#) sections, e.g. `"{:04d}".format(144)` yields `'0144'` and `"{: .3f}".format(1.0/3.0)` yields `'0.333'`.

## How do I modify a string in place?

You can't, because strings are immutable. In most situations, you should simply construct a new string from the various parts you want to assemble it from. However, if you need an object with the ability to modify in-place unicode data, try using an [io.StringIO](#) object or the [array](#) module:

```
>>> import io
>>> s = "Hello, world"
>>> sio = io.StringIO(s)
>>> sio.getvalue()
'Hello, world'
>>> sio.seek(7)
7
>>> sio.write("there!")
6
>>> sio.getvalue()
'Hello, there!'

>>> import array
>>> a = array.array('u', s)
>>> print(a)
array('u', 'Hello, world')
>>> a[0] = 'y'
>>> print(a)
array('u', 'yello, world')
>>> a.tounicode()
'yello, world'
```

## How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions.

The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the primary technique used to emulate a case construct:

```
def a():  
    pass
```

```
def b():  
    pass
```

```
dispatch = {'go': a, 'stop': b} # Note lack of par  
  
dispatch[get_input()]() # Note trailing parens to
```

- Use the built-in function `getattr()`:

```
import foo  
getattr(foo, 'bar')()
```

Note that `getattr()` works on any object, including classes, class instances, modules, and so on.

This is used in several places in the standard library, like this:

```
class Foo:  
    def do_foo(self):  
        ...  
  
    def do_bar(self):  
        ...  
  
f = getattr(foo_instance, 'do_' + opname)  
f()
```

- Use `locals()` to resolve the function name:

```
def myFunc():  
    print("hello")  
  
fname = "myFunc"
```

```
f = locals()[fname]
f()
```

## Is there an equivalent to Perl's `chomp()` for removing trailing newlines from strings?

You can use `S.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `S` without removing other trailing whitespace. If the string `S` represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

```
>>> lines = ("line 1 \r\n"
...          "\r\n"
...          "\r\n")
>>> lines.rstrip("\n\r")
'line 1 '
```

Since this is typically only desired when reading text one line at a time, using `S.rstrip()` this way works well.

## Is there a `scanf()` or `sscanf()` equivalent?

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the `split()` method of string objects and then convert decimal strings to numeric values using `int()` or `float()`. `split()` supports an optional “sep” parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C's `sscanf` and better suited for the task.

## What does ‘UnicodeDecodeError’ or ‘UnicodeEncodeError’ error mean?

See the [Unicode HOWTO](#).

## Can I end a raw string with an odd number of backslashes?

A raw string ending with an odd number of backslashes will escape the string's quote:

```
>>> r'C:\this\will\not\work\  
File "<stdin>", line 1  
    r'C:\this\will\not\work\  
        ^
```

SyntaxError: unterminated string literal (detected at li

There are several workarounds for this. One is to use regular strings and double the backslashes:

```
>>> 'C:\\this\\will\\work\\'  
'C:\\this\\will\\work\\'
```

Another is to concatenate a regular string containing an escaped backslash to the raw string:

```
>>> r'C:\this\will\work' '\\'  
'C:\\this\\will\\work\\'
```

It is also possible to use `os.path.join()` to append a backslash on Windows:

```
>>> os.path.join(r'C:\this\will\work', '')  
'C:\\this\\will\\work\\'
```

Note that while a backslash will “escape” a quote for the purposes of determining where the raw string ends, no escaping occurs when interpreting the value of the raw string. That is, the backslash remains present in the value of the raw string:

```
>>> r'backslash\'preserved'  
"backslash\\'preserved"
```

Also see the specification in the [language reference](#).

# Performance

## My program is too slow. How do I speed it up?

That's a tough one, in general. First, here are a list of things to remember before diving further:

- Performance characteristics vary across Python implementations. This FAQ focuses on [CPython](#).
- Behaviour can vary across operating systems, especially when talking about I/O or multi-threading.
- You should always find the hot spots in your program *before* attempting to optimize any code (see the [profile](#) module).
- Writing benchmark scripts will allow you to iterate quickly when searching for improvements (see the [timeit](#) module).
- It is highly recommended to have good code coverage (through unit testing or any other technique) before potentially introducing regressions hidden in sophisticated optimizations.

That being said, there are many tricks to speed up Python code. Here are some general principles which go a long way towards reaching acceptable performance levels:

- Making your algorithms faster (or changing to faster ones) can yield much larger benefits than trying to sprinkle micro-optimization tricks all over your code.
- Use the right data structures. Study documentation for the [Built-in Types](#) and the [collections](#) module.
- When the standard library provides a primitive for doing something, it is likely (although not guaranteed) to be faster than any alternative you may come up with. This is doubly true for primitives written in C, such as builtins and some extension types. For example, be sure to use either the [list.sort\(\)](#) built-in method or the related [sorted\(\)](#) function to do sorting (and see the [Sorting HOW TO](#) for examples of moderately advanced usage).
- Abstractions tend to create indirections and force the interpreter to work more. If the levels of indirection outweigh the amount of useful work done, your program will be

slower. You should avoid excessive abstraction, especially under the form of tiny functions or methods (which are also often detrimental to readability).

If you have reached the limit of what pure Python can allow, there are tools to take you further away. For example, [Cython](https://cython.org) [https://cython.org] can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms. Cython can take advantage of compilation (and optional type annotations) to make your code significantly faster than when interpreted. If you are confident in your C programming skills, you can also [write a C extension module](#) yourself.

## See also

The wiki page devoted to [performance tips](https://wiki.python.org/moin/PythonSpeed/PerformanceTips) [https://wiki.python.org/moin/PythonSpeed/PerformanceTips].

## What is the most efficient way to concatenate many strings together?

**str** and **bytes** objects are immutable, therefore concatenating many strings together is inefficient as each concatenation creates a new object. In the general case, the total runtime cost is quadratic in the total string length.

To accumulate many **str** objects, the recommended idiom is to place them into a list and call **str.join()** at the end:

```
chunks = []
for s in my_strings:
    chunks.append(s)
result = ''.join(chunks)
```

(another reasonably efficient idiom is to use [io.StringIO](#))

To accumulate many **bytes** objects, the recommended idiom is to extend a **bytearray** object using in-place concatenation (the **+=** operator):

```
result = bytearray()
for b in my_bytes_objects:
    result += b
```

## Sequences (Tuples/Lists)

### How do I convert between tuples and lists?

The type constructor `tuple(seq)` converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, `tuple([1, 2, 3])` yields `(1, 2, 3)` and `tuple('abc')` yields `('a', 'b', 'c')`. If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call `tuple()` when you aren't sure that an object is already a tuple.

The type constructor `list(seq)` converts any sequence or iterable into a list with the same items in the same order. For example, `list((1, 2, 3))` yields `[1, 2, 3]` and `list('abc')` yields `['a', 'b', 'c']`. If the argument is a list, it makes a copy just like `seq[:]` would.

### What's a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices -1 is the last index and -2 is the penultimate (next to last) index and so forth. Think of `seq[-n]` as the same as `seq[len(seq)-n]`.

Using negative indices can be very convenient. For example `S[:-1]` is all of the string except for its last character, which is useful for removing the trailing newline from a string.

### How do I iterate over a sequence in reverse order?

Use the `reversed()` built-in function:

```
for x in reversed(sequence):
    ... # do something with x ...
```

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

## How do you remove duplicates from a list?

See the Python Cookbook for a long discussion of many ways to do this:

<https://code.activestate.com/recipes/52560/>

If you don't mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```
if mylist:
    mylist.sort()
    last = mylist[-1]
    for i in range(len(mylist)-2, -1, -1):
        if last == mylist[i]:
            del mylist[i]
        else:
            last = mylist[i]
```

If all elements of the list may be used as set keys (i.e. they are all [hashable](#)) this is often faster

```
mylist = list(set(mylist))
```

This converts the list into a set, thereby removing duplicates, and then back into a list.

## How do you remove multiple items from a list

As with removing duplicates, explicitly iterating in reverse with a delete condition is one possibility. However, it is easier and faster to use slice replacement with an implicit or explicit forward iteration. Here are three variations.:

```
mylist[:] = filter(keep_function, mylist)
```

```
mylist[:] = (x for x in mylist if keep_condition)
mylist[:] = [x for x in mylist if keep_condition]
```

The list comprehension may be fastest.

## How do you make an array in Python?

Use a list:

```
["this", 1, "is", "an", "array"]
```

Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The `array` module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that [NumPy](https://numpy.org/) [https://numpy.org/] and other third party packages define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate *cons cells* using tuples:

```
lisp_list = ("like", ("this", ("example", None) ) )
```

If mutability is desired, you could use lists instead of tuples. Here the analogue of a Lisp *car* is `lisp_list[0]` and the analogue of *cdr* is `lisp_list[1]`. Only do this if you're sure you really need to, because it's usually a lot slower than using Python lists.

## How do I create a multidimensional list?

You probably tried to make a multidimensional array like this:

```
>>> A = [[None] * 2] * 3
```

This looks correct if you print it:

```
>>> A
[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```
>>> A[0][0] = 5
>>> A
[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with `*` doesn't create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```
A = [None] * 3
for i in range(3):
    A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:

```
w, h = 2, 3
A = [[None] * w for i in range(h)]
```

Or, you can use an extension that provides a matrix datatype; [NumPy](https://numpy.org/) [https://numpy.org/] is the best known.

## How do I apply a method or function to a sequence of objects?

To call a method or function and accumulate the return values in a list, a [list comprehension](#) is an elegant solution:

```
result = [obj.method() for obj in mylist]

result = [function(obj) for obj in mylist]
```

To just run the method or function without saving the return values, a plain **for** loop will suffice:

```
for obj in mylist:
    obj.method()
```

```
for obj in mylist:
    function(obj)
```

## Why does `a_tuple[i] += ['item']` raise an exception when the addition works?

This is because of a combination of the fact that augmented assignment operators are *assignment* operators, and the difference between mutable and immutable objects in Python.

This discussion applies in general when augmented assignment operators are applied to elements of a tuple that point to mutable objects, but we'll use a `list` and `+=` as our exemplar.

If you wrote:

```
>>> a_tuple = (1, 2)
>>> a_tuple[0] += 1
Traceback (most recent call last):
```

```
...
```

```
TypeError: 'tuple' object does not support item assignment
```

The reason for the exception should be immediately clear: `1` is added to the object `a_tuple[0]` points to (`1`), producing the result object, `2`, but when we attempt to assign the result of the computation, `2`, to element `0` of the tuple, we get an error because we can't change what an element of a tuple points to.

Under the covers, what this augmented assignment statement is doing is approximately this:

```
>>> result = a_tuple[0] + 1
>>> a_tuple[0] = result
Traceback (most recent call last):
```

```
...
```

```
TypeError: 'tuple' object does not support item assignment
```

It is the assignment part of the operation that produces the error, since a tuple is immutable.

When you write something like:

```
>>> a_tuple = (['foo'], 'bar')
>>> a_tuple[0] += ['item']
Traceback (most recent call last):
...
TypeError: 'tuple' object does not support item assignment
```

The exception is a bit more surprising, and even more surprising is the fact that even though there was an error, the append worked:

```
>>> a_tuple[0]
['foo', 'item']
```

To see why this happens, you need to know that (a) if an object implements an `__iadd__()` magic method, it gets called when the `+=` augmented assignment is executed, and its return value is what gets used in the assignment statement; and (b) for lists, `__iadd__()` is equivalent to calling `extend()` on the list and returning the list. That's why we say that for lists, `+=` is a “shorthand” for `list.extend()`:

```
>>> a_list = []
>>> a_list += [1]
>>> a_list
[1]
```

This is equivalent to:

```
>>> result = a_list.__iadd__([1])
>>> a_list = result
```

The object pointed to by `a_list` has been mutated, and the pointer to the mutated object is assigned back to `a_list`. The end result of the assignment is a no-op, since it is a pointer to the same object that `a_list` was previously pointing to, but the assignment still happens.

Thus, in our tuple example what is happening is equivalent to:

```
>>> result = a_tuple[0].__iadd__(['item'])
>>> a_tuple[0] = result
Traceback (most recent call last):
...
TypeError: 'tuple' object does not support item assignment
```

The `__iadd__()` succeeds, and thus the list is extended, but even though `result` points to the same object that `a_tuple[0]` already points to, that final assignment still results in an error, because tuples are immutable.

## I want to do a complicated sort: can you do a Schwartzian Transform in Python?

The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its “sort value”. In Python, use the `key` argument for the `list.sort()` method:

```
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

## How can I sort one list by values from another list?

Merge them into an iterator of tuples, sort the resulting list, and then pick out the element you want.

```
>>> list1 = ["what", "I'm", "sorting", "by"]
>>> list2 = ["something", "else", "to", "sort"]
>>> pairs = zip(list1, list2)
>>> pairs = sorted(pairs)
>>> pairs
[('I'm', 'else'), ('by', 'sort'), ('sorting', 'to'), ('what', 'something')]
>>> result = [x[1] for x in pairs]
>>> result
['else', 'sort', 'to', 'something']
```

# Objects

## What is a class?

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic `Mailbox` class that provides basic accessor methods for a mailbox, and subclasses such as `MboxMailbox`, `MaildirMailbox`, `OutlookMailbox` that handle various specific mailbox formats.

## What is a method?

A method is a function on some object `x` that you normally call as `x.name(arguments...)`. Methods are defined as functions inside the class definition:

```
class C:
    def meth(self, arg):
        return arg * 2 + self.attribute
```

## What is self?

Self is merely a conventional name for the first argument of a method. A method defined as `meth(self, a, b, c)` should be called as `x.meth(a, b, c)` for some instance `x` of the class in which the definition occurs; the called method will think it is called as `meth(x, a, b, c)`.

See also [Why must 'self' be used explicitly in method definitions and calls?](#).

## How do I check if an object is an instance of a given

## class or of a subclass of it?

Use the built-in function `isinstance(obj, cls)`. You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. `isinstance(obj, (class1, class2, ...))`, and can also check whether an object is one of Python's built-in types, e.g. `isinstance(obj, str)` or `isinstance(obj, (int, float, complex))`.

Note that `isinstance()` also checks for virtual inheritance from an [abstract base class](#). So, the test will return `True` for a registered class even if hasn't directly or indirectly inherited from it. To test for "true inheritance", scan the [MRO](#) of the class:

```
from collections.abc import Mapping

class P:
    pass

class C(P):
    pass

Mapping.register(P)

>>> c = C()
>>> isinstance(c, C)           # direct
True
>>> isinstance(c, P)           # indirect
True
>>> isinstance(c, Mapping)     # virtual
True

# Actual inheritance chain
>>> type(c).__mro__
(<class 'C'>, <class 'P'>, <class 'object'>)

# Test for "true inheritance"
>>> Mapping in type(c).__mro__
False
```

Note that most programs do not use `isinstance()` on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object's class and doing a different thing based on what class it is. For example, if you have a function that does something:

```
def search(obj):
    if isinstance(obj, Mailbox):
        ... # code to search a mailbox
    elif isinstance(obj, Document):
        ... # code to search a document
    elif ...
```

A better approach is to define a `search()` method on all the classes and just call it:

```
class Mailbox:
    def search(self):
        ... # code to search a mailbox

class Document:
    def search(self):
        ... # code to search a document

obj.search()
```

## What is delegation?

Delegation is an object oriented technique (also called a design pattern). Let's say you have an object `x` and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you're interested in changing and delegates all other methods to the corresponding method of `x`.

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```
class UpperOut:

    def __init__(self, outfile):
        self._outfile = outfile

    def write(self, s):
        self._outfile.write(s.upper())

    def __getattr__(self, name):
        return getattr(self._outfile, name)
```

Here the `UpperOut` class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self._outfile.write()` method. All other methods are delegated to the underlying `self._outfile` object. The delegation is accomplished via the `__getattr__()` method; consult [the language reference](#) for more information about controlling attribute access.

Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a `__setattr__()` method too, and it must do so carefully. The basic implementation of `__setattr__()` is roughly equivalent to the following:

```
class X:
    ...
    def __setattr__(self, name, value):
        self.__dict__[name] = value
    ...
```

Most `__setattr__()` implementations must modify `self.__dict__` to store local state for self without causing an infinite recursion.

## How do I call a method defined in a base class from a derived class that extends it?

Use the built-in `super()` function:

```
class Derived(Base):
    def meth(self):
        super().meth()    # calls Base.meth
```

In the example, `super()` will automatically determine the instance from which it was called (the `self` value), look up the [method resolution order](#) (MRO) with `type(self).__mro__`, and return the next in line after `Derived` in the MRO: `Base`.

## How can I organize my code to make it easier to change the base class?

You could assign the base class to an alias and derive from the alias. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use. Example:

```
class Base:
    ...

BaseAlias = Base

class Derived(BaseAlias):
    ...
```

## How do I create static class data and static class methods?

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value to the attribute, you have to explicitly use the class name in the assignment:

```
class C:
    count = 0    # number of times C.__init__ called
```

```
def __init__(self):
    C.count = C.count + 1

def getcount(self):
    return C.count # or return self.count
```

`c.count` also refers to `C.count` for any `c` such that `isinstance(c, C)` holds, unless overridden by `c` itself or by some class on the base-class search path from `c.__class__` back to `C`.

Caution: within a method of `C`, an assignment like `self.count = 42` creates a new and unrelated instance named “count” in `self`’s own dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

```
C.count = 314
```

Static methods are possible:

```
class C:
    @staticmethod
    def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
```

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:

```
def getcount():
    return C.count
```

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

## How can I overload constructors (or methods) in Python?

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you'd write

```
class C {
    C() { cout << "No arguments\n"; }
    C(int i) { cout << "Argument is " << i << "\n"; }
}
```

In Python you have to write a single constructor that catches all cases using default arguments. For example:

```
class C:
    def __init__(self, i=None):
        if i is None:
            print("No arguments")
        else:
            print("Argument is", i)
```

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.

```
def __init__(self, *args):
    ...
```

The same approach works for all method definitions.

## **I try to use `_spam` and I get an error about `_SomeClassName_spam`.**

Variable names with double leading underscores are “mangled” to provide a simple but effective way to define class private variables. Any identifier of the form `__spam` (at least two leading underscores, at most one trailing underscore) is textually replaced with `__classname_spam`, where `classname` is the current class name with any leading underscores stripped.

This doesn't guarantee privacy: an outside user can still deliberately access the `__classname_spam` attribute, and private values are visible in the object's `__dict__`. Many Python programmers never bother to use private variable names at all.

## My class defines `__del__` but it is not called when I delete the object.

There are several possible reasons for this.

The `del` statement does not necessarily call `__del__()` – it simply decrements the object’s reference count, and if this reaches zero `__del__()` is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your `__del__()` method may be called at an inconvenient and random time. This is inconvenient if you’re trying to reproduce a problem. Worse, the order in which object’s `__del__()` methods are executed is arbitrary. You can run `gc.collect()` to force a collection, but there *are* pathological cases where objects will never be collected.

Despite the cycle collector, it’s still a good idea to define an explicit `close()` method on objects to be called whenever you’re done with them. The `close()` method can then remove attributes that refer to subobjects. Don’t call `__del__()` directly – `__del__()` should call `close()` and `close()` should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the `weakref` module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need them!).

Finally, if your `__del__()` method raises an exception, a warning message is printed to `sys.stderr`.

## How do I get a list of all instances of a given class?

Python does not keep track of all instances of a class (or of a built-

in type). You can program the class's constructor to keep track of all instances by keeping a list of weak references to each instance.

## Why does the result of `id()` appear to be not unique?

The `id()` builtin returns an integer that is guaranteed to be unique during the lifetime of the object. Since in CPython, this is the object's memory address, it happens frequently that after an object is deleted from memory, the next freshly created object is allocated at the same position in memory. This is illustrated by this example:

```
>>> id(1000)
13901272
>>> id(2000)
13901272
```

The two ids belong to different integer objects that are created before, and deleted immediately after execution of the `id()` call. To be sure that objects whose id you want to examine are still alive, create another reference to the object:

```
>>> a = 1000; b = 2000
>>> id(a)
13901272
>>> id(b)
13891296
```

## When can I rely on identity tests with the `is` operator?

The `is` operator tests for object identity. The test `a is b` is equivalent to `id(a) == id(b)`.

The most important property of an identity test is that an object is always identical to itself, `a is a` always returns `True`. Identity tests are usually faster than equality tests. And unlike equality tests, identity tests are guaranteed to return a boolean `True` or `False`.

However, identity tests can *only* be substituted for equality tests when object identity is assured. Generally, there are three

circumstances where identity is guaranteed:

1) Assignments create new names but do not change object identity. After the assignment `new = old`, it is guaranteed that `new` is `old`.

2) Putting an object in a container that stores object references does not change object identity. After the list assignment `s[0] = x`, it is guaranteed that `s[0]` is `x`.

3) If an object is a singleton, it means that only one instance of that object can exist. After the assignments `a = None` and `b = None`, it is guaranteed that `a is b` because `None` is a singleton.

In most other circumstances, identity tests are inadvisable and equality tests are preferred. In particular, identity tests should not be used to check constants such as `int` and `str` which aren't guaranteed to be singletons:

```
>>> a = 1000
>>> b = 500
>>> c = b + 500
>>> a is c
False
```

```
>>> a = 'Python'
>>> b = 'Py'
>>> c = b + 'thon'
>>> a is c
False
```

Likewise, new instances of mutable containers are never identical:

```
>>> a = []
>>> b = []
>>> a is b
False
```

In the standard library code, you will see several common patterns for correctly using identity tests:

1) As recommended by [PEP 8](https://peps.python.org/pep-0008/) [https://peps.python.org/pep-0008/], an identity test is the preferred way to check for `None`. This reads like plain English in code and avoids confusion with other objects that may have boolean values that evaluate to false.

2) Detecting optional arguments can be tricky when `None` is a valid input value. In those situations, you can create a singleton sentinel object guaranteed to be distinct from other objects. For example, here is how to implement a method that behaves like `dict.pop()`:

```
_sentinel = object()

def pop(self, key, default=_sentinel):
    if key in self:
        value = self[key]
        del self[key]
        return value
    if default is _sentinel:
        raise KeyError(key)
    return default
```

3) Container implementations sometimes need to augment equality tests with identity tests. This prevents the code from being confused by objects such as `float('NaN')` that are not equal to themselves.

For example, here is the implementation of `collections.abc.Sequence.__contains__()`:

```
def __contains__(self, value):
    for v in self:
        if v is value or v == value:
            return True
    return False
```

## How can a subclass control what data is stored in an immutable instance?

When subclassing an immutable type, override the `__new__()`

method instead of the `__init__()` method. The latter only runs *after* an instance is created, which is too late to alter data in an immutable instance.

All of these immutable classes have a different signature than their parent class:

```
from datetime import date

class FirstOfMonthDate(date):
    "Always choose the first day of the month"
    def __new__(cls, year, month, day):
        return super().__new__(cls, year, month, 1)

class NamedInt(int):
    "Allow text names for some numbers"
    xlat = {'zero': 0, 'one': 1, 'ten': 10}
    def __new__(cls, value):
        value = cls.xlat.get(value, value)
        return super().__new__(cls, value)

class TitleStr(str):
    "Convert str to name suitable for a URL path"
    def __new__(cls, s):
        s = s.lower().replace(' ', '-')
        s = ''.join([c for c in s if c.isalnum() or c == '-'])
        return super().__new__(cls, s)
```

The classes can be used like this:

```
>>> FirstOfMonthDate(2012, 2, 14)
FirstOfMonthDate(2012, 2, 1)
>>> NamedInt('ten')
10
>>> NamedInt(20)
20
>>> TitleStr('Blog: Why Python Rocks')
'blog-why-python-rocks'
```

## How do I cache method calls?

The two principal tools for caching methods are `functools.cached_property()` and `functools.lru_cache()`. The former stores results at the instance level and the latter at the class level.

The *cached\_property* approach only works with methods that do not take any arguments. It does not create a reference to the instance. The cached method result will be kept only as long as the instance is alive.

The advantage is that when an instance is no longer used, the cached method result will be released right away. The disadvantage is that if instances accumulate, so too will the accumulated method results. They can grow without bound.

The *lru\_cache* approach works with methods that have `hashable` arguments. It creates a reference to the instance unless special efforts are made to pass in weak references.

The advantage of the least recently used algorithm is that the cache is bounded by the specified *maxsize*. The disadvantage is that instances are kept alive until they age out of the cache or until the cache is cleared.

This example shows the various techniques:

```
class Weather:
    "Lookup weather information on a government website"

    def __init__(self, station_id):
        self._station_id = station_id
        # The _station_id is private and immutable

    def current_temperature(self):
        "Latest hourly observation"
        # Do not cache this because old results
        # can be out of date.
```

```

@cached_property
def location(self):
    "Return the longitude/latitude coordinates of the station"
    # Result only depends on the station_id

@lru_cache(maxsize=20)
def historic_rainfall(self, date, units='mm'):
    "Rainfall on a given date"
    # Depends on the station_id, date, and units.

```

The above example assumes that the *station\_id* never changes. If the relevant instance attributes are mutable, the *cached\_property* approach can't be made to work because it cannot detect changes to the attributes.

To make the *lru\_cache* approach work when the *station\_id* is mutable, the class needs to define the `__eq__()` and `__hash__()` methods so that the cache can detect relevant attribute updates:

```

class Weather:
    "Example with a mutable station identifier"

    def __init__(self, station_id):
        self.station_id = station_id

    def change_station(self, station_id):
        self.station_id = station_id

    def __eq__(self, other):
        return self.station_id == other.station_id

    def __hash__(self):
        return hash(self.station_id)

@lru_cache(maxsize=20)
def historic_rainfall(self, date, units='cm'):
    "Rainfall on a given date"
    # Depends on the station_id, date, and units.

```

# Modules

## How do I create a .pyc file?

When a module is imported for the first time (or when the source file has changed since the current compiled file was created) a .pyc file containing the compiled code should be created in a `__pycache__` subdirectory of the directory containing the .py file. The .pyc file will have a filename that starts with the same name as the .py file, and ends with .pyc, with a middle component that depends on the particular python binary that created it. (See [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/] for details.)

One reason that a .pyc file may not be created is a permissions problem with the directory containing the source file, meaning that the `__pycache__` subdirectory cannot be created. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server.

Unless the `PYTHONDONTWRITEBYTECODE` environment variable is set, creation of a .pyc file is automatic if you're importing a module and Python has the ability (permissions, free space, etc...) to create a `__pycache__` subdirectory and write the compiled module to that subdirectory.

Running Python on a top level script is not considered an import and no .pyc will be created. For example, if you have a top-level module `foo.py` that imports another module `xyz.py`, when you run `foo` (by typing `python foo.py` as a shell command), a .pyc will be created for `xyz` because `xyz` is imported, but no .pyc file will be created for `foo` since `foo.py` isn't being imported.

If you need to create a .pyc file for `foo` – that is, to create a .pyc file for a module that is not imported – you can, using the `py_compile` and `compileall` modules.

The `py_compile` module can manually compile any module. One way is to use the `compile()` function in that module interactively:

```
>>> import py_compile
>>> py_compile.compile('foo.py')
```

This will write the `.pyc` to a `__pycache__` subdirectory in the same location as `foo.py` (or you can override that with the optional parameter `cfile`).

You can also automatically compile all files in a directory or directories using the `compileall` module. You can do it from the shell prompt by running `compileall.py` and providing the path of a directory containing Python files to compile:

```
python -m compileall .
```

## How do I find the current module name?

A module can find out its own module name by looking at the predefined global variable `__name__`. If this has the value `'__main__'`, the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking `__name__`:

```
def main():
    print('Running test...')
    ...

if __name__ == '__main__':
    main()
```

## How can I have modules that mutually import each other?

Suppose you have the following modules:

```
foo.py:

from bar import bar_var
foo_var = 1
```

`bar.py:`

```
from foo import foo_var  
bar_var = 2
```

The problem is that the interpreter will perform the following steps:

- main imports `foo`
- Empty globals for `foo` are created
- `foo` is compiled and starts executing
- `foo` imports `bar`
- Empty globals for `bar` are created
- `bar` is compiled and starts executing
- `bar` imports `foo` (which is a no-op since there already is a module named `foo`)
- The import mechanism tries to read `foo_var` from `foo` globals, to set `bar.foo_var = foo.foo_var`

The last step fails, because Python isn't done with interpreting `foo` yet and the global symbol dictionary for `foo` is still empty.

The same thing happens when you use `import foo`, and then try to access `foo.foo_var` in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of `from <module> import ...`, and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as `<module>.<name>`.

Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don't need imported base classes)
- `import` statements
- active code (including globals that are initialized from imported values).

Van Rossum doesn't like this approach much because the imports

appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

**`_import_('x.y.z')` returns `<module 'x'>`; how do I get `z`?**

Consider using the convenience function `import_module()` from `importlib` instead:

```
z = importlib.import_module('x.y.z')
```

**When I edit an imported module and reimport it, the changes don't show up. Why does this happen?**

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn't, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force re-reading of a changed module, do this:

```
import importlib
import modname
importlib.reload(modname)
```

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

```
from modname import some_objects
```

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will *not* be updated to use the new class definition. This can result in the following paradoxical behaviour:

```
>>> import importlib
```

```
>>> import cls
>>> c = cls.C() # Create an instance of C
>>> importlib.reload(cls)
<module 'cls' from 'cls.py'>
>>> isinstance(c, cls.C) # isinstance is false?!?
False
```

The nature of the problem is made clear if you print out the “identity” of the class objects:

```
>>> hex(id(c.__class__))
'0x7352a0'
>>> hex(id(cls.C))
'0x4198d0'
```

- Why are colons required for the if/while/def/class statements?
- Why does Python allow commas at the end of lists and tuples?

## Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```
if (x <= y)
    x++;
    y--;
z++;
```

Only the `x++` statement is executed if the condition is true, but the indentation leads many to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering as to why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place

the braces. After becoming used to reading and writing code using a particular style, it is normal to feel somewhat uneasy when reading (or being required to write) in a different one.

Many coding styles place begin/end brackets on a line by themselves. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20–30 lines). 20 lines of Python can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of declarations and the high-level data types are also responsible – but the indentation-based syntax certainly helps.

## Why am I getting strange results with simple arithmetic operations?

See the next question.

## Why are floating-point calculations so inaccurate?

Users are often surprised by results like this:

```
>>> 1.2 - 1.0
0.19999999999999996
```

and think it is a bug in Python. It's not. This has little to do with Python, and much more to do with how the underlying platform handles floating-point numbers.

The `float` type in CPython uses a C `double` for storage. A `float` object's value is stored in binary floating-point with a fixed precision (typically 53 bits) and Python uses C operations, which in turn rely on the hardware implementation in the processor, to perform floating-point operations. This means that as far as floating-point operations are concerned, Python behaves like many popular languages including C and Java.

Many numbers that can be written easily in decimal notation

cannot be expressed exactly in binary floating-point. For example, after:

```
>>> x = 1.2
```

the value stored for `x` is a (very good) approximation to the decimal value `1.2`, but is not exactly equal to it. On a typical machine, the actual stored value is:

```
1.0011001100110011001100110011001100110011001100110011001100110011
```

which is exactly:

```
1.1999999999999999555910790149937383830547332763671875
```

The typical precision of 53 bits provides Python floats with 15–16 decimal digits of accuracy.

For a fuller explanation, please see the [floating point arithmetic](#) chapter in the Python tutorial.

## Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as “elemental” as numbers. No amount of activity will change the value `8` to anything else, and in Python, no amount of activity will change the string “eight” to anything else.

## Why must ‘self’ be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it's more obvious that you are using a method or instance attribute instead of a local variable. Reading `self.x` or `self.meth()` makes it absolutely clear that an instance variable or method is used even if you don't know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you'd have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an `m_` prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the `::` operator – in Python you can write `baseclass.methodname(self, <argument list>)`. This is particularly useful for `__init__()` methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren't explicitly declared global), there has to be some way to tell the interpreter that an assignment was meant to assign to an instance variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn't have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don't have to search the instance's directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.

## Why can't I use an assignment in an expression?

Starting in Python 3.8, you can!

Assignment expressions using the walrus operator `:=` assign a variable in an expression:

```
while chunk := fp.read(200):  
    print(chunk)
```

See [PEP 572](https://peps.python.org/pep-0572/) [https://peps.python.org/pep-0572/] for more information.

## Why does Python use methods for some functionality (e.g. `list.index()`) but functions for other (e.g. `len(list)`)?

As Guido said:

(a) For some operations, prefix notation just reads better than postfix – prefix (and infix!) operations have a long tradition in mathematics which likes notations where the visuals help the mathematician thinking about a problem. Compare the easy with which we rewrite a formula like  $x*(a+b)$  into  $x*a + x*b$  to the clumsiness of doing the same thing using a raw OO notation.

(b) When I read code that says `len(x)` I *know* that it is asking for the length of something. This tells me two things: the result is an integer, and the argument is some kind of container. To the contrary, when I read `x.len()`, I have to already know that `x` is some kind of container implementing an interface or inheriting from a class that has a standard `len()`. Witness the confusion we occasionally have when a class that is not implementing a mapping has a `get()` or `keys()` method, or something that isn't a file has a `write()` method.

—<https://mail.python.org/pipermail/>

## Why is `join()` a string method instead of a list or tuple method?

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the string module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

```
", ".join(['1', '2', '4', '8', '16'])
```

which gives the result:

```
"1, 2, 4, 8, 16"
```

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having `split()` as a string method, since in that case it is easy to see that

```
"1, 2, 4, 8, 16".split(", ")
```

is an instruction to a string literal to return the substrings delimited by the given separator (or, by default, arbitrary runs of white space).

`join()` is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself

between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself. Similar methods exist for bytes and bytearray objects.

## How fast are exceptions?

A `try/except` block is extremely efficient if no exceptions are raised. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```
try:
    value = mydict[key]
except KeyError:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn't the case, you coded it like this:

```
if key in mydict:
    value = mydict[key]
else:
    value = mydict[key] = getvalue(key)
```

For this specific case, you could also use `value = dict.setdefault(key, getvalue(key))`, but only if the `getvalue()` call is cheap enough because it is evaluated in all cases.

## Why isn't there a switch or case statement in Python?

You can do this easily enough with a sequence of `if... elif... elif... else`. For literal values, or constants within a namespace, you can also use a `match ... case` statement.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to

functions to call. For example:

```
functions = {'a': function_1,
            'b': function_2,
            'c': self.method_1}
```

```
func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```
class MyVisitor:
    def visit_a(self):
        ...

    def dispatch(self, value):
        method_name = 'visit_' + str(value)
        method = getattr(self, method_name)
        method()
```

It's suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming from an untrusted source, an attacker would be able to call any method on your object.

## Can't you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is [Stackless Python](https://github.com/stackless-dev/stackless/wiki) [https://github.com/stackless-dev/stackless/wiki], which has a completely redesigned interpreter loop that avoids the C stack.

## Why can't lambda expressions contain statements?

Python lambda expressions cannot contain statements because Python's syntactic framework can't handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you're too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda instead of a locally defined function is that you don't need to invent a name for the function – but that's just a local variable to which the function object (which is exactly the same type of object that a lambda expression yields) is assigned!

## Can Python be compiled to machine code, C or some other language?

**Cython** [<https://cython.org/>] compiles a modified version of Python with optional annotations into C extensions. **Nuitka** [<https://www.nuitka.net/>] is an up-and-coming compiler of Python into C++ code, aiming to support the full Python language.

## How does Python manage memory?

The details of Python memory management depend on the implementation. The standard implementation of Python, **CPython**, uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The **gc** module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Other implementations (such as **Jython** [<https://www.jython.org/>] or **PyPy** [<https://www.pypy.org/>]), however, can rely on a different

mechanism such as a full-blown garbage collector. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

In some Python implementations, the following code (which is fine in CPython) will probably run out of file descriptors:

```
for file in very_long_list_of_files:
    f = open(file)
    c = f.read(1)
```

Indeed, using CPython's reference counting and destructor scheme, each new assignment to `f` closes the previous file. With a traditional GC, however, those file objects will only get collected (and closed) at varying and possibly long intervals.

If you want to write code that will work with any Python implementation, you should explicitly close the file or use the `with` statement; this will work regardless of memory management scheme:

```
for file in very_long_list_of_files:
    with open(file) as f:
        c = f.read(1)
```

## Why doesn't CPython use a more traditional garbage collection scheme?

For one thing, this is not a C standard feature and hence it's not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for *most* common platforms, not for all of them, and although it is mostly transparent, it isn't completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it's fine to replace the standard `malloc()` and `free()` with versions provided by the GC library, an application embedding Python may want to have its *own* substitute for `malloc()` and `free()`, and may not want Python's. Right now, CPython works with anything

that implements `malloc()` and `free()` properly.

## Why isn't all memory freed when CPython exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.

## Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal `records` or C `structs`; they're small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can't replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list's elements.

Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.

## How are lists implemented in CPython?

CPython's lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array's length in a list head structure.

This makes indexing a list `a[i]` an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don't require an actual resize.

## How are dictionaries implemented in CPython?

CPython's dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the `hash()` built-in function. The hash code varies widely depending on the key and a per-process seed; for example, `'Python'` could hash to `-539294296` while `'python'`, a string that differs by a single bit, could hash to `1142331976`. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you're storing keys that all have different hash values, this means that dictionaries take constant time –  $O(1)$ , in Big-O notation – to retrieve a key.

# Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can't tell that it was being used as a dictionary key, it can't move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won't be found because its hash value is different. If you tried to look up the old value it wouldn't be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function `tuple(L)` creates a tuple with the same entries as the list `L`. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn't work because if you construct a new list with the same value it won't be found; e.g.:

```
mydict = {[1, 2]: '12'}  
print(mydict[[1, 2]])
```

would raise a **KeyError** exception because the id of the `[1, 2]` used in the second line differs from that in the first line. In other words, dictionary keys should be compared using `==`, not using **is**.

- Make a copy when using a list as a key. This doesn't work because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an infinite loop.
- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an

important invariant of dictionaries: every value in `d.keys()` is usable as a key of the dictionary.

- Mark lists as read-only once they are used as a dictionary key. The problem is that it's not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a `__eq__()` and a `__hash__()` method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

```
class ListWrapper:
    def __init__(self, the_list):
        self.the_list = the_list

    def __eq__(self, other):
        return self.the_list == other.the_list

    def __hash__(self):
        l = self.the_list
        result = 98767 - len(l)*555
        for i, el in enumerate(l):
            try:
                result = result + (hash(el) % 9999999) *
            except Exception:
                result = (result % 7777777) + i * 333
        return result
```

Note that the hash computation is complicated by the possibility that some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if `o1 == o2` (ie `o1.__eq__(o2)` is `True`) then `hash(o1) == hash(o2)` (ie, `o1.__hash__() == o2.__hash__()`), regardless of whether the object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of **ListWrapper**, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don't do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.

## Why doesn't `list.sort()` return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won't be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

If you want to return a new list, use the built-in `sorted()` function instead. This function creates a new list from a provided iterable, sorts it and returns it. For example, here's how to iterate over the keys of a dictionary in sorted order:

```
for key in sorted(mydict):  
    ... # do whatever with mydict[key]...
```

## How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and `issubclass()` to check whether an instance or a class implements a particular ABC. The `collections.abc` module defines a set of useful ABCs such as `Iterable`, `Container`, and `MutableMapping`.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple “self test.” Even modules which use complex external interfaces can often be tested in isolation using trivial “stub” emulations of the external interface. The `doctest` and `unittest` modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would. In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the `list.append()` method is expected to add new elements to the end of some internal list; an interface specification cannot test that your `list.append()` implementation will actually do this correctly, but it’s trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code to make it easily tested. One increasingly popular technique, test-driven development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.

## Why is there no goto?

In the 1970s people realized that unrestricted goto could lead to messy “spaghetti” code that was hard to understand and revise. In a high-level language, it is also unneeded as long as there are ways to branch (in Python, with `if` statements and `or`, `and`, and `if/`

**else** expressions) and loop (with **while** and **for** statements, possibly containing **continue** and **break**).

One can also use exceptions to provide a “structured goto” that works even across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the `go` or `goto` constructs of C, Fortran, and other languages. For example:

```
class label(Exception): pass    # declare a label

try:
    ...
    if condition: raise label()  # goto label
    ...
except label:  # where to goto
    pass
...
```

This doesn’t allow you to jump into the middle of a loop, but that’s usually considered an abuse of `goto` anyway. Use sparingly.

## Why can’t raw strings (r-strings) end with a backslash?

More precisely, they can’t end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you’re trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```
f = open("/mydir/file.txt") # works fine!
```

If you're trying to build a pathname for a DOS command, try e.g. one of

```
dir = r"\this\is\my\dos\dir" "\\ "  
dir = r"\this\is\my\dos\dir\ "[:-1]  
dir = "\\this\\is\\my\\dos\\dir\\"
```

## Why doesn't Python have a “with” statement for attribute assignments?

Python has a **with** statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some languages have a construct that looks like this:

```
with obj:  
    a = 1 # equivalent to obj.a = 1  
    total = total + 1 # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it's possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler *always* knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```
def foo(a):  
    with a:  
        print(x)
```

The snippet assumes that `a` must have a member attribute called `x`. However, there is nothing in Python that tells the interpreter this. What should happen if `a` is, let us say, an integer? If there is a global variable named `x`, will it be used inside the `with` block? As you see, the dynamic nature of Python makes such choices much harder.

The primary benefit of `with` and similar language features (reduction of code volume) can, however, easily be achieved in Python by assignment. Instead of:

```
function(args).mydict[index][index].a = 21
function(args).mydict[index][index].b = 42
function(args).mydict[index][index].c = 63
```

write this:

```
ref = function(args).mydict[index][index]
ref.a = 21
ref.b = 42
ref.c = 63
```

This also has the side-effect of increasing execution speed because name bindings are resolved at run-time in Python, and the second version only needs to perform the resolution once.

Similar proposals that would introduce syntax to further reduce code volume, such as using a ‘leading dot’, have been rejected in favour of explicitness (see <https://mail.python.org/pipermail/python-ideas/2016-May/040070.html>).

## Why don't generators support the with statement?

For technical reasons, a generator used directly as a context manager would not work correctly. When, as is most common, a generator is used as an iterator run to completion, no closing is needed. When it is, wrap it as `contextlib.closing(generator)` in the `with` statement.

## Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```
if a == b
    print(a)
```

versus

```
if a == b:
    print(a)
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it's a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.

## Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```
[1, 2, 3,]
('a', 'b', 'c',)
d = {
    "A": [1, 5],
    "B": [6, 7], # last trailing comma is optional but
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread

across multiple lines, it's easier to add more elements because you don't have to remember to add a comma to the previous line. The lines can also be reordered without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```
x = [  
    "fee",  
    "fie"  
    "foo",  
    "fum"  
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source of error.

Allowing the trailing comma may also make programmatic code generation easier.

## General Library Questions

### How do I find a module or application to perform task X?

Check [the Library Reference](#) to see if there's a relevant standard library module. (Eventually you'll learn what's in the standard library and will be able to skip this step.)

For third-party packages, search the [Python Package Index](https://pypi.org) [https://pypi.org] or try [Google](https://www.google.com) [https://www.google.com] or another web search engine. Searching for “Python” plus a keyword or two for your topic of interest will usually find something helpful.

### Where is the `math.py` (`socket.py`, `regex.py`, etc.)

## source file?

If you can't find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like `mathmodule.c`, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);
2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);
3. modules written in C and linked with the interpreter; to get a list of these, type:

```
import sys
print(sys.builtin_module_names)
```

## How do I make a Python script executable on Unix?

You need to do two things: the script file's mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the `env` program. Almost all Unix variants support the following, assuming the Python interpreter is

in a directory on the user's **PATH**:

```
#!/usr/bin/env python
```

*Don't* do this for CGI scripts. The **PATH** variable for CGI scripts is often very minimal, so you need to use the actual absolute pathname of the interpreter.

Occasionally, a user's environment is so full that the **/usr/bin/env** program fails; or there's no **env** program at all. In that case, you can try the following hack (due to Alex Rezinsky):

```
#!/bin/sh
""" : """
exec python $0 ${1+"$@"}
```

The minor disadvantage is that this defines the script's `__doc__` string. However, you can fix that by adding

```
__doc__ = """...Whatever..."""
```

## Is there a **curses/termcap** package for Python?

For Unix variants: The standard Python source distribution comes with a **curses** module in the **Modules** [<https://github.com/python/cpython/tree/3.12/Modules>] subdirectory, though it's not compiled by default. (Note that this is not available in the Windows distribution – there is no **curses** module for Windows.)

The **curses** module supports basic **curses** features as well as many additional functions from **ncurses** and **SVS** **curses** such as colour, alternative character set support, pads, and mouse support. This means the module isn't compatible with operating systems that only have BSD **curses**, but there don't seem to be any currently maintained OSes that fall into this category.

## Is there an equivalent to C's **onexit()** in Python?

The **atexit** module provides a register function that is similar to C's **onexit()**.

## Why don't my signal handlers work?

The most common problem is that the signal handler is declared with the wrong argument list. It is called as

```
handler(signum, frame)
```

so it should be declared with two parameters:

```
def handler(signum, frame):  
    ...
```

## Common tasks

### How do I test a Python program or component?

Python comes with two testing frameworks. The **doctest** module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The **unittest** module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

To make testing easier, you should use good modular design in your program. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```
if __name__ == "__main__":  
    main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of function and class behaviours, you should write test functions that exercise the behaviours. A test suite that automates a sequence of tests can be associated with each module. This sounds like a lot of work, but since Python is so terse and flexible it's surprisingly easy. You can make coding much more pleasant and fun by writing your test functions in parallel with the “production code”, since this makes it easy to find bugs and even design flaws earlier.

“Support modules” that are not intended to be the main module of a program may include a self-test of the module.

```
if __name__ == "__main__":  
    self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using “fake” interfaces implemented in Python.

## How do I create documentation from doc strings?

The **pydoc** module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is **epydoc** [<https://epydoc.sourceforge.net/>]. **Sphinx** [<https://www.sphinx-doc.org>] can also include docstring content.

## How do I get a single keypress at a time?

For Unix variants there are several solutions. It's straightforward to do this using **curses**, but **curses** is a fairly large module to learn.

# Threads

## How do I program using threads?

Be sure to use the **threading** module and not the **\_thread** module. The **threading** module builds convenient abstractions on top of the low-level primitives provided by the **\_thread** module.

## None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that's long enough for all the threads to finish:

```
import threading, time

def thread_task(name, n):
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i), 10))
    T.start()

time.sleep(10)  # <-----!
```

But now (on many platforms) the threads don't run in parallel, but appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn't start a new thread until the previous thread is blocked.

A simple fix is to add a tiny sleep to the start of the run function:

```
def thread_task(name, n):
    time.sleep(0.001)  # <-----!
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i), 10))
    T.start()

time.sleep(10)
```

Instead of trying to guess a good delay value for `time.sleep()`,

it's better to use some kind of semaphore mechanism. One idea is to use the `queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

## How do I parcel out work among a bunch of worker threads?

The easiest way is to use the `concurrent.futures` module, especially the `ThreadPoolExecutor` class.

Or, if you want fine control over the dispatching algorithm, you can write your own logic manually. Use the `queue` module to create a queue containing a list of jobs. The `Queue` class maintains a list of objects and has a `.put(obj)` method that adds items to the queue and a `.get()` method to return them. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here's a trivial example:

```
import threading, queue, time

# The worker thread gets jobs off the queue.  When the q
# assumes there will be no more work and exits.
# (Realistically workers will run until terminated.)
def worker():
    print('Running worker')
    time.sleep(0.1)
    while True:
        try:
            arg = q.get(block=False)
        except queue.Empty:
            print('Worker', threading.current_thread(),
                  'print('queue empty')
            break
        else:
            print('Worker', threading.current_thread(),
                  'print('running with argument', arg)
```

```

        time.sleep(0.5)

# Create queue
q = queue.Queue()

# Start a pool of 5 workers
for i in range(5):
    t = threading.Thread(target=worker, name='worker %i' % i)
    t.start()

# Begin adding work to the queue
for i in range(50):
    q.put(i)

# Give threads time to run
print('Main thread sleeping')
time.sleep(5)

```

When run, this will produce the following output:

```

Running worker
Running worker
Running worker
Running worker
Running worker
Main thread sleeping
Worker <Thread(worker 1, started 130283832797456)> runni
Worker <Thread(worker 2, started 130283824404752)> runni
Worker <Thread(worker 3, started 130283816012048)> runni
Worker <Thread(worker 4, started 130283807619344)> runni
Worker <Thread(worker 5, started 130283799226640)> runni
Worker <Thread(worker 1, started 130283832797456)> runni
...

```

Consult the module's documentation for more details; the [Queue](#) class provides a featureful interface.

## What kinds of global value mutation are thread-safe?

A [global interpreter lock](#) (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via [sys.setswitchinterval\(\)](#). Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that “look atomic” really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```
L.append(x)
L1.extend(L2)
x = L[i]
x = L.pop()
L1[i:j] = L2
L.sort()
x = y
x.field = y
D[x] = y
D1.update(D2)
D.keys()
```

These aren't:

```
i = i+1
L.append(L[-1])
L[i] = L[j]
D[x] = D[x] + 1
```

Operations that replace other objects may invoke those other objects' [\\_\\_del\\_\\_\(\)](#) method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!

## Can't we get rid of the Global Interpreter Lock?

The [global interpreter lock](#) (GIL) is often seen as a hindrance to Python's deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

Back in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the "free threading" patches) that removed the GIL and replaced it with fine-grained locking. Adam Olsen recently did a similar experiment in his [python-safethread](https://code.google.com/archive/p/python-safethread) [https://code.google.com/archive/p/python-safethread] project. Unfortunately, both experiments exhibited a sharp drop in single-thread performance (at least 30% slower), due to the amount of fine-grained locking necessary to compensate for the removal of the GIL.

This doesn't mean that you can't make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple *processes* rather than multiple *threads*. The [ProcessPoolExecutor](#) class in the new [concurrent.futures](#) module provides an easy way of doing so; the [multiprocessing](#) module provides a lower-level API in case you want more control over dispatching of tasks.

Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done. Some standard library modules such as [zlib](#) and [hashlib](#) already do this.

It has been suggested that the GIL should be a per-interpreter-state lock rather than truly global; interpreters then wouldn't be able to share objects. Unfortunately, this isn't likely to happen either. It would be a tremendous amount of work, because many object implementations currently have global state. For example, small integers and short strings are cached; these caches would have to be moved to the interpreter state. Other object types have their own free list; these free lists would have to be moved to the interpreter

state. And so on.

And I doubt that it can even be done in finite time, because the same problem exists for 3rd party extensions. It is likely that 3rd party extensions are being written at a faster rate than you can convert them to store all their global state in the interpreter state.

And finally, once you have multiple interpreters not sharing any state, what have you gained over running each interpreter in a separate process?

## Input and Output

### How do I delete a file? (And other file questions...)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the `os` module. The two functions are identical; `unlink()` is simply the name of the Unix system call for this function.

To remove a directory, use `os.rmdir()`; use `os.mkdir()` to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don't exist. `os.removedirs(path)` will remove intermediate directories as long as they're empty; if you want to delete an entire directory tree and its contents, use `shutil.rmtree()`.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "rb+")`, and use `f.truncate(offset)`; `offset` defaults to the current seek position. There's also `os.ftruncate(fd, offset)` for files opened with `os.open()`, where `fd` is the file descriptor (a small integer).

The `shutil` module also contains a number of functions to work on files including `copyfile()`, `copytree()`, and `rmtree()`.

### How do I copy a file?

The `shutil` module contains a `copyfile()` function. Note that on Windows NTFS volumes, it does not copy [alternate data streams](https://en.wikipedia.org/wiki/NTFS#Alternate_data_stream_(ADS)) [https://en.wikipedia.org/wiki/NTFS#Alternate\_data\_stream\_(ADS)] nor [resource forks](https://en.wikipedia.org/wiki/Resource_fork) [https://en.wikipedia.org/wiki/Resource\_fork] on macOS HFS+ volumes, though both are now rarely used. It also doesn't copy file permissions and metadata, though using `shutil.copy2()` instead will preserve most (though not all) of it.

## How do I read (or write) binary data?

To read or write complex binary data formats, it's best to use the `struct` module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```
import struct

with open(filename, "rb") as f:
    s = f.read(8)
    x, y, z = struct.unpack(">hhl", s)
```

The `'>'` in the format string forces big-endian data; the letter `'h'` reads one “short integer” (2 bytes), and `'l'` reads one “long integer” (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or floats), you can also use the `array` module.

### Note

To read and write binary data, it is mandatory to open the file in binary mode (here, passing `"rb"` to `open()`). If you use `"r"` instead (the default), the file will be open in text mode and `f.read()` will return `str` objects rather than `bytes` objects.

## I can't seem to use `os.read()` on a pipe created with

## os.popen(); why?

`os.read()` is a low-level function which takes a file descriptor, a small integer representing the opened file. `os.popen()` creates a high-level file object, the same type returned by the built-in `open()` function. Thus, to read  $n$  bytes from a pipe  $p$  created with `os.popen()`, you need to use `p.read(n)`.

## How do I access the serial (RS232) port?

For Win32, OSX, Linux, BSD, Jython, IronPython:

<https://pypi.org/project/pyserial/>

For Unix, see a Usenet post by Mitch Chapman:

[https://groups.google.com/groups?  
selm=34A04430.CF9@ohioee.com](https://groups.google.com/groups?selm=34A04430.CF9@ohioee.com)

## Why doesn't closing sys.stdout (stdin, stderr) really close it?

Python [file objects](#) are a high-level layer of abstraction on low-level C file descriptors.

For most file objects you create in Python via the built-in `open()` function, `f.close()` marks the Python file object as being closed from Python's point of view, and also arranges to close the underlying C file descriptor. This also happens automatically in `f`'s destructor, when `f` becomes garbage.

But `stdin`, `stdout` and `stderr` are treated specially by Python, because of the special status also given to them by C. Running `sys.stdout.close()` marks the Python-level file object as being closed, but does *not* close the associated C file descriptor.

To close the underlying C file descriptor for one of these three, you should first be sure that's what you really want to do (e.g., you may confuse extension modules trying to do I/O). If it is, use `os.close()`:

```
os.close(stdin.fileno())
os.close(stdout.fileno())
os.close(stderr.fileno())
```

Or you can use the numeric constants 0, 1 and 2, respectively.

## Network/Internet Programming

### What WWW tools are there for Python?

See the chapters titled [Internet Protocols and Support](#) and [Internet Data Handling](#) in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

A summary of available frameworks is maintained by Paul Boddie at <https://wiki.python.org/moin/WebProgramming>.

Cameron Laird maintains a useful set of pages about Python web technologies at [https://web.archive.org/web/20210224183619/http://phaseit.net/claird/comp.lang.python/web\\_python](https://web.archive.org/web/20210224183619/http://phaseit.net/claird/comp.lang.python/web_python).

### How can I mimic CGI form submission (METHOD = POST)?

I would like to retrieve web pages that are the result of POSTing a form. Is there existing code that would let me do this easily?

Yes. Here's a simple example that uses `urllib.request`:

```
#!/usr/local/bin/python
```

```
import urllib.request
```

```
# build the query string
```

```
qs = "First=Josephine&MI=Q&Last=Public"
```

```
# connect and send the server a path
```

```
req = urllib.request.urlopen('http://www.some-server.out
```

```
                                '/cgi-bin/some-cgi-script',  
with req:  
    msg, hdrs = req.read(), req.info()
```

Note that in general for percent-encoded POST operations, query strings must be quoted using `urllib.parse.urlencode()`. For example, to send `name=Guy Steele, Jr.:`

```
>>> import urllib.parse  
>>> urllib.parse.urlencode({'name': 'Guy Steele, Jr.'})  
'name=Guy+Steele%2C+Jr.'
```

## See also

[HOWTO Fetch Internet Resources Using The urllib Package](#) for extensive examples.

## What module should I use to help with generating HTML?

You can find a collection of useful links on the [Web Programming wiki page](https://wiki.python.org/moin/WebProgramming) [https://wiki.python.org/moin/WebProgramming].

## How do I send mail from a Python script?

Use the standard library module `smtplib`.

Here's a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```
import sys, smtplib  
  
fromaddr = input("From: ")  
toaddrs  = input("To: ").split(',')  
print("Enter message, end with ^D:")  
msg = ''  
while True:  
    line = sys.stdin.readline()  
    if not line:
```

```

        break
    msg += line

# The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
server.quit()

```

A Unix-only alternative uses `sendmail`. The location of the `sendmail` program varies between systems; sometimes it is `/usr/lib/sendmail`, sometimes `/usr/sbin/sendmail`. The `sendmail` manual page will help you out. Here's some sample code:

```

import os

SENDMAIL = "/usr/sbin/sendmail" # sendmail location
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n") # blank line separating headers from body
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
    print("Sendmail exit status", sts)

```

## How do I avoid blocking in the `connect()` method of a socket?

The `select` module is commonly used to help with asynchronous I/O on sockets.

To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the `connect()`, you will either connect immediately (unlikely) or get an exception that contains the error number as `.errno`. `errno.EINPROGRESS` indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the `connect_ex()` method to avoid creating an exception. It will just return the `errno` value. To poll, you can call `connect_ex()` again later – `0` or `errno.EISCONN` indicate that you're connected – or you can pass this socket to `select.select()` to check if it's writable.

## Note

The `asyncio` module provides a general purpose single-threaded and concurrent asynchronous library, which can be used for writing non-blocking network code. The third-party `Twisted` [<https://twisted.org/>] library is a popular and feature-rich alternative.

## Databases

### Are there any interfaces to database packages in Python?

Yes.

Interfaces to disk-based hashes such as `DBM` and `GDBM` are also included with standard Python. There is also the `sqlite3` module, which provides a lightweight disk-based relational database.

Support for most relational databases is available. See the [DatabaseProgramming wiki page](https://wiki.python.org/moin/DatabaseProgramming) [<https://wiki.python.org/moin/DatabaseProgramming>] for details.

### How do you implement persistent objects in Python?

The `pickle` library module solves this in a very general way (though you still can't store things like open files, sockets or windows), and the `shelve` library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects.

## Mathematics and Numerics

## How do I generate random numbers in Python?

The standard module `random` implements a random number generator. Usage is simple:

```
import random
random.random()
```

This returns a random floating point number in the range [0, 1).

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range [a, b).
- `uniform(a, b)` chooses a floating point number in the range [a, b).
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses a random element from a given sequence.
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly.

There's also a `Random` class you can instantiate to create independent multiple random number generators.

  - [How do I find undefined g++ symbols \\_builtin\\_new or \\_pure\\_virtual?](#)
  - [Can I create an object class with some methods implemented in C and others in Python \(e.g. through inheritance\)?](#)

## Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document [Extending and Embedding the Python Interpreter](#).

Most intermediate or advanced Python books will also cover this topic.

## Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C" { ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.

## Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you're trying to do.

[Cython](https://cython.org) [https://cython.org] and its relative [Pyrex](https://www.csse.canterbury.ac.nz/greg.ewing/python/Pyrex/) [https://www.csse.canterbury.ac.nz/greg.ewing/python/Pyrex/] are compilers that accept a slightly modified form of Python and generate the corresponding C code. Cython and Pyrex make it possible to write an extension without having to learn Python's C API.

If you need to interface to some C or C++ library for which no Python extension currently exists, you can try wrapping the library's data types and functions with a tool such as [SWIG](https://www.swig.org) [https://www.swig.org], [SIP](https://riverbankcomputing.com/software/sip/intro) [https://riverbankcomputing.com/software/sip/intro], [CXX](https://cxx.sourceforge.net/) [https://cxx.sourceforge.net/], [Boost](https://www.boost.org/libs/python/doc/index.html) [https://www.boost.org/libs/python/doc/index.html], or [Weave](https://github.com/scipy/weave) [https://github.com/scipy/weave] are also alternatives for wrapping C++ libraries.

## How can I execute arbitrary Python statements from C?

The highest-level function to do this is `PyRun_SimpleString()` which takes a single string argument to be executed in the context of the module `__main__` and returns 0 for success and -1 when an exception occurred (including `SyntaxError`). If you want more control, use `PyRun_String()`; see the source for `PyRun_SimpleString()` in `Python/pythonrun.c`.

## How can I evaluate an arbitrary Python expression from C?

Call the function `PyRun_String()` from the previous question with the start symbol `Py_eval_input`; it parses an expression, evaluates it and returns its value.

## How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, `PyTuple_Size()` returns its length and `PyTuple_GetItem()` returns the item at a specified index. Lists have similar functions, `PyList_Size()` and `PyList_GetItem()`.

For bytes, `PyBytes_Size()` returns its length and `PyBytes_AsStringAndSize()` provides a pointer to its value and its length. Note that Python bytes objects may contain null bytes so C's `strlen()` should not be used.

To test the type of an object, first make sure it isn't `NULL`, and then use `PyBytes_Check()`, `PyTuple_Check()`, `PyList_Check()`, etc.

There is also a high-level API to Python objects which is provided by the so-called 'abstract' interface – read `Include/abstract.h` for further details. It allows interfacing with any kind of Python sequence using calls like `PySequence_Length()`, `PySequence_GetItem()`, etc. as well as many other useful protocols such as numbers (`PyNumber_Index()` et al.) and mappings in the `PyMapping` APIs.

## How do I use `Py_BuildValue()` to create a tuple of arbitrary length?

You can't. Use `PyTuple_Pack()` instead.

## How do I call an object's method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```
PyObject *  
PyObject_CallMethod(PyObject *object, const char *method,  
                    const char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_DECREF()`ing the return value.

To call, e.g., a file object's “seek” method with arguments 10, 0 (assuming the file object pointer is “f”):

```
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);  
if (res == NULL) {  
    ... an exception occurred ...  
}  
else {  
    Py_DECREF(res);  
}
```

Note that since `PyObject_CallObject()` *always* wants a tuple for the argument list, to call a function without arguments, pass “()” for the format, and to call a function with one argument, surround the argument in parentheses, e.g. “(i)”.

## How do I catch the output from `PyErr_Print()` (or anything that prints to

## stdout/stderr)?

In Python code, define an object that supports the `write()` method. Assign this object to `sys.stdout` and `sys.stderr`. Call `print_error`, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the `io.StringIO` class:

```
>>> import io, sys
>>> sys.stdout = io.StringIO()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(sys.stdout.getvalue())
foo
hello world!
```

A custom object to do the same would look like this:

```
>>> import io, sys
>>> class StdoutCatcher(io.TextIOBase):
...     def __init__(self):
...         self.data = []
...     def write(self, stuff):
...         self.data.append(stuff)
...
>>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(''.join(sys.stdout.data))
foo
hello world!
```

## How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```
module = PyImport_ImportModule("<modulename>");
```

If the module hasn't been imported yet (i.e. it is not yet present in `sys.modules`), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn't enter the module into any namespace – it only ensures it has been initialized and is stored in `sys.modules`.

You can then access the module's attributes (i.e. any name defined in the module) as follows:

```
attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling `PyObject_SetAttrString()` to assign to variables in the module also works.

## How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading [the “Extending and Embedding” document](#). Realize that for the Python run-time system, there isn't a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, see [Writing C is hard; are there any alternatives?](#).

## I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn't seem worth the effort.)

## How do I debug an extension?

When using GDB with dynamically loaded extensions, you can't set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
gdb) run myscript.py
gdb) continue # repeat until your extension is loaded
gdb) finish   # so that your extension is loaded
gdb) br myfunction.c:50
gdb) continue
```

## I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python don't include the `/usr/lib/python2.x/config/` directory, which contains various files required for compiling Python extensions.

For Red Hat, install the `python-devel` RPM to get the necessary files.

For Debian, run `apt-get install python-dev`.

## How do I tell “incomplete input” from “invalid input”?

Sometimes you want to emulate the Python interactive interpreter's behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an “if” statement or you didn't close your parentheses or triple string quotes), but it gives

you a syntax error message immediately when the input is invalid.

In Python you can use the `codeop` module, which approximates the parser's behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call `PyRun_InteractiveLoop()` (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the `PyOS_ReadlineFunctionPointer()` to point at your custom input function. See `Modules/readline.c` and `Parser/myreadline.c` for more hints.

## How do I find undefined g++ symbols `__builtin_new` or `__pure_virtual`?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change `LINKCC` in the Python `Modules Makefile`), and link your extension module using g++ (e.g., `g++ -shared -o mymodule.so mymodule.o`).

## Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

Yes, you can inherit from built-in classes such as `int`, `list`, `dict`, etc.

The Boost Python Library (BPL, <https://www.boost.org/libs/python/doc/index.html>) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).

## How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance.

Unless you use some sort of integrated development environment, you will end up *typing* Windows commands into what is referred to as a “Command prompt window”. Usually you can create such a window from your search bar by searching for `cmd`. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

```
C:\>
```

The letter may be different, and there might be other things after it, so you might just as easily see something like:

```
D:\YourName\Projects\Python>
```

depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python *interpreter*. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “py” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command `py` and hitting return:

```
C:\Users\YourName> py
```

You should then see something like:

```
Python 3.6.4 (v3.6.4:d48eceb, Dec 19 2017, 06:04:45) [MS
Type "help", "copyright", "credits" or "license" for mor
>>>
```

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python’s strongest features. Check it by entering a few expressions of your choice and seeing the results:

```
>>> print("Hello")
Hello
>>> "Hello" * 3
'HelloHelloHello'
```

Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, call the `exit()` function or hold the `Ctrl` key down while you enter a `z`, then hit the “Enter” key to get back to your Windows command prompt.

You may also find that you have a Start-menu entry such as *Start ▶ Programs ▶ Python 3.x ▶ Python (command line)* that results in you seeing the `>>>` prompt in a new window. If so, the window will disappear after you call the `exit()` function or enter the `Ctrl-Z` character; Windows is running a single “python” command in the window, and closes it when you terminate the interpreter.

Now that we know the `py` command is recognized, you can give your Python script to it. You’ll have to give either an absolute or a relative path to the Python script. Let’s say your Python script is located in your desktop and is named `hello.py`, and your command prompt is nicely opened in your home directory so you’re seeing something similar to:

```
C:\Users\YourName>
```

So now you’ll ask the `py` command to give your script to Python by typing `py` followed by your script path:

```
C:\Users\YourName> py Desktop\hello.py
hello
```

## How do I make Python scripts executable?

On Windows, the standard Python installer already associates the `.py` extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (`D:\Program Files\Python\python.exe "%1" %*`). This is enough to make scripts executable from the command prompt as ‘`foo.py`’. If you’d rather be able to execute the script by simple typing ‘`foo`’ with no extension you need to add `.py` to the `PATHEXT` environment variable.

## Why does Python sometimes take so long

## to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.

## How do I make an executable from a Python script?

See [How can I create a stand-alone binary from a Python script?](#) for a list of tools that can be used to make executables.

## Is a \*.pyd file the same as a DLL?

Yes, .pyd files are dll's, but there are a few differences. If you have a DLL named `foo.pyd`, then it must have a function `PyInit_foo()`. You can then write Python “import foo”, and Python will search for `foo.pyd` (as well as `foo.py`, `foo.pyc`) and if it finds it, will attempt to call `PyInit_foo()` to initialize it. You do not link your .exe with `foo.lib`, as that would cause Windows to require the DLL to be present.

Note that the search path for `foo.pyd` is `PYTHONPATH`, not the same as the path that Windows uses to search for `foo.dll`. Also, `foo.pyd` need not be present to run your program, whereas if you linked your program with a `dll`, the `dll` is required. Of course, `foo.pyd` is required if you want to say `import foo`. In a `DLL`,

linkage is declared in the source code with `__declspec(dllexport)`. In a `.pyd`, linkage is defined in a list of available functions.

## How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do **not** build Python into your `.exe` file directly. On Windows, Python must be a DLL to handle importing modules that are themselves DLL's. (This is the first key undocumented fact.) Instead, link to `pythonNN.dll`; it is typically installed in `C:\Windows\System`. `NN` is the Python version, a number such as "33" for Python 3.3.

You can link to Python in two different ways. Load-time linking means linking against `pythonNN.lib`, while run-time linking means linking against `pythonNN.dll`. (General note: `pythonNN.lib` is the so-called "import lib" corresponding to `pythonNN.dll`. It merely defines symbols for the linker.)

Run-time linking greatly simplifies link options; everything happens at run time. Your code must load `pythonNN.dll` using the Windows `LoadLibraryEx()` routine. The code must also use access routines and data in `pythonNN.dll` (that is, Python's C API's) using pointers obtained by the Windows `GetProcAddress()` routine. Macros can make using these pointers transparent to any C code that calls routines in Python's C API.

2. If you use SWIG, it is easy to create a Python "extension module" that will make the app's data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link *into* your `.exe` file (!) You do **not** have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is `leo`, the init function will be called `initleo()`. If you use SWIG shadow classes, as you should, the init function will be called `initleoC()`. This initializes a mostly hidden helper class used by the shadow class.

The reason you can link the C code in step 2 into your `.exe` file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

```
#include <Python.h>
...
Py_Initialize(); // Initialize Python.
initmyAppC(); // Initialize (import) the helper cl
PyRun_SimpleString("import myApp"); // Import the
```

5. There are two problems with Python's C API which will become apparent if you use a compiler other than MSVC, the compiler used to build `pythonNN.dll`.

**Problem 1:** The so-called "Very High Level" functions that take `FILE *` arguments will not work in a multi-compiler environment because each compiler's notion of a `struct FILE` will be different. From an implementation standpoint these are very low level functions.

**Problem 2:** SWIG generates the following code when generating wrappers to void functions:

```
Py_INCREF(Py_None);
_resultobj = Py_None;
return _resultobj;
```

Alas, `Py_None` is a macro that expands to a reference to a complex data structure called `_Py_NoneStruct` inside

pythonNN.dll. Again, this code will fail in a mult-compiler environment. Replace such code by:

```
return Py_BuildValue("");
```

It may be possible to use SWIG's `%typemap` command to make the change automatically, though I have not been able to get this to work (I'm a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app's windowing system. Rather, you (or the `wxPythonWindow` class) should create a “native” interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python's i/o to `_any_` object that supports read and write, so all you need is a Python object (defined in your extension module) that contains `read()` and `write()` methods.

## How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, [PEP 8](https://peps.python.org/pep-0008/) [https://peps.python.org/pep-0008/], recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take *Tools* ▶ *Options* ▶ *Tabs*, and for file type “Default” set “Tab size” and “Indent size” to 4, and select the “Insert spaces” radio button.

Python raises `IndentationError` or `TabError` if mixed tabs and spaces are causing problems in leading whitespace. You may also run the `tabnanny` module to check a directory tree in batch mode.

## How do I check for a keypress without blocking?

Use the `msvcrt` module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.

## How do I solve the missing `api-ms-win-crt-runtime-l1-1-0.dll` error?

This can occur on Python 3.5 and later when using Windows 8.1 or earlier without all updates having been installed. First ensure your operating system is supported and is up to date, and if that does not resolve the issue, visit the [Microsoft support page](https://support.microsoft.com/en-us/help/3118401/) [https://support.microsoft.com/en-us/help/3118401/] for guidance on manually installing the C Runtime update.

  - [Tkinter questions](#)
    - [How do I freeze Tkinter applications?](#)
    - [Can I have Tk events handled while waiting for I/O?](#)
    - [I can't get key bindings to work in Tkinter: why?](#)

## General GUI Questions

### What GUI toolkits exist for Python?

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called [tkinter](#). This is probably the easiest to install (since it comes included with most [binary distributions](#) [<https://www.python.org/downloads/>] of Python) and use. For more info about Tk, including pointers to the source, see the [Tcl/Tk home page](#) [<https://www.tcl.tk>]. Tcl/Tk is fully portable to the macOS, Windows, and Unix platforms.

Depending on what platform(s) you are aiming at, there are also several alternatives. A [list of cross-platform](#) [[https://wiki.python.org/moin/GuiProgramming#Cross-Platform\\_Frameworks](https://wiki.python.org/moin/GuiProgramming#Cross-Platform_Frameworks)] and [platform-specific](#) [[https://wiki.python.org/moin/GuiProgramming#Platform-specific\\_Frameworks](https://wiki.python.org/moin/GuiProgramming#Platform-specific_Frameworks)] GUI frameworks can be found on the python wiki.

## Tkinter questions

## How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the **TCL\_LIBRARY** and **TK\_LIBRARY** environment variables.

To get truly stand-alone applications, the Tcl scripts that form the library have to be integrated into the application as well. One tool supporting that is SAM (stand-alone modules), which is part of the Tix distribution (<https://tix.sourceforge.net/>).

Build Tix with SAM enabled, perform the appropriate call to **Tclsam\_init()**, etc. inside Python's `Modules/tkappinit.c`, and link with `libtclsam` and `libtkSAM` (you might include the Tix libraries as well).

## Can I have Tk events handled while waiting for I/O?

On platforms other than Windows, yes, and you don't even need threads! But you'll have to restructure your I/O code a bit. Tk has the equivalent of Xt's **XtAddInput()** call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. See [File Handlers](#).

## I can't get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers [bound](#) to events with the **bind()** method don't get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn't have "keyboard focus". Check out the Tk documentation for the focus command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the `takefocus` option).

# “Why is Python Installed on my Computer?” FAQ

## What is Python?

Python is a programming language. It's used for many different applications. It's used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it's also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the [Beginner's Guide to Python](https://wiki.python.org/moin/BeginnersGuide) [https://wiki.python.org/moin/BeginnersGuide].

## Why is Python installed on my machine?

If you find Python installed on your system but don't remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you'll have to figure out who's been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. There are many such applications, from GUI programs to network servers and administrative scripts.
- Some Windows machines also have Python installed. At this writing we're aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq's administrative tools are written in Python.
- Many Unix-compatible operating systems, such as macOS and some Linux distributions, have Python installed by default; it's included in the base installation.

# Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application's uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.

# Glossary

>>>

The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

...

Can refer to:

- The default Python prompt of the interactive shell when entering the code for an indented code block, when within a pair of matching left and right delimiters (parentheses, square brackets, curly braces or triple quotes), or after specifying a decorator.
- The [Ellipsis](#) built-in constant.

## 2to3

A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as [lib2to3](#); a standalone entry point is provided as `Tools/scripts/2to3`. See [2to3 — Automated Python 2 to 3 code translation](#).

## abstract base class

Abstract base classes complement [duck-typing](#) by providing a way to define interfaces when other techniques like [hasattr\(\)](#) would be clumsy or subtly wrong (for example with [magic methods](#)). ABCs introduce virtual subclasses, which are classes that don't inherit from a class but are still recognized by [isinstance\(\)](#) and [issubclass\(\)](#); see the [abc](#) module documentation. Python comes with many built-

in ABCs for data structures (in the `collections.abc` module), numbers (in the `numbers` module), streams (in the `io` module), import finders and loaders (in the `importlib.abc` module). You can create your own ABCs with the `abc` module.

## annotation

A label associated with a variable, a class attribute or a function parameter or return value, used by convention as a [type hint](#).

Annotations of local variables cannot be accessed at runtime, but annotations of global variables, class attributes, and functions are stored in the `__annotations__` special attribute of modules, classes, and functions, respectively.

See [variable annotation](#), [function annotation](#), [PEP 484](#) [<https://peps.python.org/pep-0484/>] and [PEP 526](#) [<https://peps.python.org/pep-0526/>], which describe this functionality. Also see [Annotations Best Practices](#) for best practices on working with annotations.

## argument

A value passed to a [function](#) (or [method](#)) when calling the function. There are two kinds of argument:

- *keyword argument*: an argument preceded by an identifier (e.g. `name=`) in a function call or passed as a value in a dictionary preceded by `**`. For example, `3` and `5` are both keyword arguments in the following calls to `complex()`:

```
complex(real=3, imag=5)
complex(**{'real': 3, 'imag': 5})
```

- *positional argument*: an argument that is not a keyword argument. Positional arguments can appear at the beginning of an argument list and/or be passed as elements of an [iterable](#) preceded by `*`. For example, `3` and `5` are both positional arguments in the following

calls:

```
complex(3, 5)
complex(*(3, 5))
```

Arguments are assigned to the named local variables in a function body. See the [Calls](#) section for the rules governing this assignment. Syntactically, any expression can be used to represent an argument; the evaluated value is assigned to the local variable.

See also the [parameter](#) glossary entry, the FAQ question on [the difference between arguments and parameters](#), and [PEP 362](#) [<https://peps.python.org/pep-0362/>].

## asynchronous context manager

An object which controls the environment seen in an [async with](#) statement by defining [\\_\\_aenter\\_\\_\(\)](#) and [\\_\\_aexit\\_\\_\(\)](#) methods. Introduced by [PEP 492](#) [<https://peps.python.org/pep-0492/>].

## asynchronous generator

A function which returns an [asynchronous generator iterator](#). It looks like a coroutine function defined with [async def](#) except that it contains [yield](#) expressions for producing a series of values usable in an [async for](#) loop.

Usually refers to an asynchronous generator function, but may refer to an *asynchronous generator iterator* in some contexts. In cases where the intended meaning isn't clear, using the full terms avoids ambiguity.

An asynchronous generator function may contain [await](#) expressions as well as [async for](#), and [async with](#) statements.

## asynchronous generator iterator

An object created by a [asynchronous generator](#) function.

This is an [asynchronous iterator](#) which when called using the

`__anext__()` method returns an awaitable object which will execute the body of the asynchronous generator function until the next `yield` expression.

Each `yield` temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the *asynchronous generator iterator* effectively resumes with another awaitable returned by `__anext__()`, it picks up where it left off. See [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/] and [PEP 525](https://peps.python.org/pep-0525/) [https://peps.python.org/pep-0525/].

## asynchronous iterable

An object, that can be used in an `async for` statement. Must return an *asynchronous iterator* from its `__aiter__()` method. Introduced by [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## asynchronous iterator

An object that implements the `__aiter__()` and `__anext__()` methods. `__anext__()` must return an *awaitable* object. `async for` resolves the awaitables returned by an asynchronous iterator's `__anext__()` method until it raises a `StopAsyncIteration` exception. Introduced by [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## attribute

A value associated with an object which is usually referenced by name using dotted expressions. For example, if an object *o* has an attribute *a* it would be referenced as *o.a*.

It is possible to give an object an attribute whose name is not an identifier as defined by [Identifiers and keywords](#), for example using `setattr()`, if the object allows it. Such an attribute will not be accessible using a dotted expression, and would instead need to be retrieved with `getattr()`.

## awaitable

An object that can be used in an `await` expression. Can be a *coroutine* or an object with an `__await__()` method. See

also [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## BDFL

Benevolent Dictator For Life, a.k.a. [Guido van Rossum](https://gvanrossum.github.io/) [https://gvanrossum.github.io/], Python's creator.

## binary file

A [file object](#) able to read and write [bytes-like objects](#). Examples of binary files are files opened in binary mode ('rb', 'wb' or 'rb+'), `sys.stdin.buffer`, `sys.stdout.buffer`, and instances of `io.BytesIO` and `gzip.GzipFile`.

See also [text file](#) for a file object able to read and write `str` objects.

## borrowed reference

In Python's C API, a borrowed reference is a reference to an object, where the code using the object does not own the reference. It becomes a dangling pointer if the object is destroyed. For example, a garbage collection can remove the last [strong reference](#) to the object and so destroy it.

Calling `Py_INCREF()` on the [borrowed reference](#) is recommended to convert it to a [strong reference](#) in-place, except when the object cannot be destroyed before the last usage of the borrowed reference. The `Py_NewRef()` function can be used to create a new [strong reference](#).

## bytes-like object

An object that supports the [Buffer Protocol](#) and can export a C-contiguous buffer. This includes all `bytes`, `bytearray`, and `array.array` objects, as well as many common `memoryview` objects. Bytes-like objects can be used for various operations that work with binary data; these include compression, saving to a binary file, and sending over a socket.

Some operations need the binary data to be mutable. The documentation often refers to these as “read-write bytes-like

objects”. Example mutable buffer objects include [bytearray](#) and a [memoryview](#) of a [bytearray](#). Other operations require the binary data to be stored in immutable objects (“read-only bytes-like objects”); examples of these include [bytes](#) and a [memoryview](#) of a [bytes](#) object.

## bytecode

Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in `.pyc` files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a [virtual machine](#) that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for [the dis module](#).

## callable

A callable is an object that can be called, possibly with a set of arguments (see [argument](#)), with the following syntax:

```
callable(argument1, argument2, argumentN)
```

A [function](#), and by extension a [method](#), is a callable. An instance of a class that implements the `__call__()` method is also a callable.

## callback

A subroutine function which is passed as an argument to be executed at some point in the future.

## class

A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

## class variable

A variable defined in a class and intended to be modified only at class level (i.e., not in an instance of the class).

## complex number

An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of  $-1$ ), often written  $i$  in mathematics or  $j$  in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a  $j$  suffix, e.g.,  $3+1j$ . To get access to complex equivalents of the `math` module, use `cmath`. Use of complex numbers is a fairly advanced mathematical feature. If you're not aware of a need for them, it's almost certain you can safely ignore them.

## context manager

An object which controls the environment seen in a `with` statement by defining `__enter__()` and `__exit__()` methods. See [PEP 343](https://peps.python.org/pep-0343/) [https://peps.python.org/pep-0343/].

## context variable

A variable which can have different values depending on its context. This is similar to Thread-Local Storage in which each execution thread may have a different value for a variable. However, with context variables, there may be several contexts in one execution thread and the main usage for context variables is to keep track of variables in concurrent asynchronous tasks. See `contextvars`.

## contiguous

A buffer is considered contiguous exactly if it is either C-*contiguous* or Fortran *contiguous*. Zero-dimensional buffers are C and Fortran contiguous. In one-dimensional arrays, the items must be laid out in memory next to each other, in order of increasing indexes starting from zero. In multidimensional C-contiguous arrays, the last index varies the fastest when visiting items in order of memory address. However, in

Fortran contiguous arrays, the first index varies the fastest.

## coroutine

Coroutines are a more generalized form of subroutines. Subroutines are entered at one point and exited at another point. Coroutines can be entered, exited, and resumed at many different points. They can be implemented with the `async def` statement. See also [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## coroutine function

A function which returns a `coroutine` object. A coroutine function may be defined with the `async def` statement, and may contain `await`, `async for`, and `async with` keywords. These were introduced by [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## CPython

The canonical implementation of the Python programming language, as distributed on [python.org](https://www.python.org) [https://www.python.org]. The term “CPython” is used when necessary to distinguish this implementation from others such as Jython or IronPython.

## decorator

A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are `classmethod()` and `staticmethod()`.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```
def f(arg):
    ...
f = staticmethod(f)

@staticmethod
def f(arg):
```

...

The same concept exists for classes, but is less commonly used there. See the documentation for [function definitions](#) and [class definitions](#) for more about decorators.

## descriptor

Any object which defines the methods `__get__()`, `__set__()`, or `__delete__()`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using `a.b` to get, set or delete an attribute looks up the object named `b` in the class dictionary for `a`, but if `b` is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors' methods, see [Implementing Descriptors](#) or the [Descriptor How To Guide](#).

## dictionary

An associative array, where arbitrary keys are mapped to values. The keys can be any object with `__hash__()` and `__eq__()` methods. Called a hash in Perl.

## dictionary comprehension

A compact way to process all or part of the elements in an iterable and return a dictionary with the results. `results = {n: n ** 2 for n in range(10)}` generates a dictionary containing key `n` mapped to value `n ** 2`. See [Displays for lists, sets and dictionaries](#).

## dictionary view

The objects returned from `dict.keys()`, `dict.values()`, and `dict.items()` are called dictionary views. They provide a dynamic view on the dictionary's entries, which means that when the dictionary changes, the view reflects these changes. To force the dictionary view to become a full list use `list(dictview)`. See [Dictionary](#)

[view objects.](#)

## docstring

A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the `__doc__` attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

## duck-typing

A programming style which does not look at an object's type to determine if it has the right interface; instead, the method or attribute is simply called or used ("If it looks like a duck and quacks like a duck, it must be a duck.") By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using `type()` or `isinstance()`. (Note, however, that duck-typing can be complemented with [abstract base classes](#).) Instead, it typically employs `hasattr()` tests or [EAFP](#) programming.

## EAFP

Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many `try` and `except` statements. The technique contrasts with the [LBYL](#) style common to many other languages such as C.

## expression

A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also [statements](#) which cannot be used as expressions, such as `while`. Assignments are also statements,

not expressions.

## extension module

A module written in C or C++, using Python's C API to interact with the core and with user code.

## f-string

String literals prefixed with `'f'` or `'F'` are commonly called “f-strings” which is short for [formatted string literals](#). See also [PEP 498](https://peps.python.org/pep-0498/) [https://peps.python.org/pep-0498/].

## file object

An object exposing a file-oriented API (with methods such as `read()` or `write()`) to an underlying resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another type of storage or communication device (for example standard input/output, in-memory buffers, sockets, pipes, etc.). File objects are also called *file-like objects* or *streams*.

There are actually three categories of file objects: raw [binary files](#), buffered [binary files](#) and [text files](#). Their interfaces are defined in the `io` module. The canonical way to create a file object is by using the `open()` function.

## file-like object

A synonym for [file object](#).

## filesystem encoding and error handler

Encoding and error handler used by Python to decode bytes from the operating system and encode Unicode to the operating system.

The filesystem encoding must guarantee to successfully decode all bytes below 128. If the file system encoding fails to provide this guarantee, API functions can raise [UnicodeError](#).

The `sys.getfilesystemencoding()` and `sys.getfilesystemencodeerrors()` functions can be

used to get the filesystem encoding and error handler.

The [filesystem encoding and error handler](#) are configured at Python startup by the `PyConfig_Read()` function: see [filesystem\\_encoding](#) and [filesystem\\_errors](#) members of `PyConfig`.

See also the [locale encoding](#).

## finder

An object that tries to find the [loader](#) for a module that is being imported.

Since Python 3.3, there are two types of finder: [meta path finders](#) for use with `sys.meta_path`, and [path entry finders](#) for use with `sys.path_hooks`.

See [PEP 302](#) [<https://peps.python.org/pep-0302/>], [PEP 420](#) [<https://peps.python.org/pep-0420/>] and [PEP 451](#) [<https://peps.python.org/pep-0451/>] for much more detail.

## floor division

Mathematical division that rounds down to nearest integer.

The floor division operator is `//`. For example, the expression `11 // 4` evaluates to `2` in contrast to the `2.75` returned by float true division. Note that `(-11) // 4` is `-3` because that is `-2.75` rounded *downward*. See [PEP 238](#) [<https://peps.python.org/pep-0238/>].

## function

A series of statements which returns some value to a caller. It can also be passed zero or more [arguments](#) which may be used in the execution of the body. See also [parameter](#), [method](#), and the [Function definitions](#) section.

## function annotation

An [annotation](#) of a function parameter or return value.

Function annotations are usually used for [type hints](#): for example, this function is expected to take two [int](#)

arguments and is also expected to have an `int` return value:

```
def sum_two_numbers(a: int, b: int) -> int:  
    return a + b
```

Function annotation syntax is explained in section [Function definitions](#).

See [variable annotation](#) and [PEP 484](#) [<https://peps.python.org/pep-0484/>], which describe this functionality. Also see [Annotations Best Practices](#) for best practices on working with annotations.

## `__future__`

A [future statement](#), `from __future__ import <feature>`, directs the compiler to compile the current module using syntax or semantics that will become standard in a future release of Python. The `__future__` module documents the possible values of *feature*. By importing this module and evaluating its variables, you can see when a new feature was first added to the language and when it will (or did) become the default:

```
>>> import __future__  
>>> __future__.division  
_Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha',
```

## garbage collection

The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles. The garbage collector can be controlled using the `gc` module.

## generator

A function which returns a [generator iterator](#). It looks like a normal function except that it contains `yield` expressions for producing a series of values usable in a for-loop or that can be retrieved one at a time with the `next()` function.

Usually refers to a generator function, but may refer to a *generator iterator* in some contexts. In cases where the intended meaning isn't clear, using the full terms avoids ambiguity.

## generator iterator

An object created by a [generator](#) function.

Each [yield](#) temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the *generator iterator* resumes, it picks up where it left off (in contrast to functions which start fresh on every invocation).

## generator expression

An expression that returns an iterator. It looks like a normal expression followed by a **for** clause defining a loop variable, range, and an optional **if** clause. The combined expression generates values for an enclosing function:

```
>>> sum(i*i for i in range(10))           # sum of sq
285
```

## generic function

A function composed of multiple functions implementing the same operation for different types. Which implementation should be used during a call is determined by the dispatch algorithm.

See also the [single dispatch](#) glossary entry, the [functools.singledispatch\(\)](#) decorator, and [PEP 443](#) [<https://peps.python.org/pep-0443/>].

## generic type

A [type](#) that can be parameterized; typically a [container class](#) such as [list](#) or [dict](#). Used for [type hints](#) and [annotations](#).

For more details, see [generic alias types](#), [PEP 483](#) [<https://peps.python.org/pep-0483/>], [PEP 484](#) [<https://peps.python.org/pep-0484/>], [PEP 585](#) [<https://peps.python.org/pep-0585/>], and the

[typing](#) module.

## GIL

See [global interpreter lock](#).

## global interpreter lock

The mechanism used by the [CPython](#) interpreter to assure that only one thread executes Python [bytecode](#) at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as [dict](#)) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

Past efforts to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity) have not been successful because performance suffered in the common single-processor case. It is believed that overcoming this performance issue would make the implementation much more complicated and therefore costlier to maintain.

## hash-based pyc

A bytecode cache file that uses the hash rather than the last-modified time of the corresponding source file to determine its validity. See [Cached bytecode invalidation](#).

## hashable

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a

set member, because these data structures use the hash value internally.

Most of Python's immutable built-in objects are hashable; mutable containers (such as lists or dictionaries) are not; immutable containers (such as tuples and frozensets) are only hashable if their elements are hashable. Objects which are instances of user-defined classes are hashable by default. They all compare unequal (except with themselves), and their hash value is derived from their `id()`.

## **IDLE**

An Integrated Development and Learning Environment for Python. **IDLE** is a basic editor and interpreter environment which ships with the standard distribution of Python.

## **immutable**

An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

## **import path**

A list of locations (or **path entries**) that are searched by the **path based finder** for modules to import. During import, this list of locations usually comes from **sys.path**, but for subpackages it may also come from the parent package's `__path__` attribute.

## **importing**

The process by which Python code in one module is made available to Python code in another module.

## **importer**

An object that both finds and loads a module; both a **finder** and **loader** object.

## interactive

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch `python` with no arguments (possibly by selecting it from your computer's main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`).

## interpreted

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also [interactive](#).

## interpreter shutdown

When asked to shut down, the Python interpreter enters a special phase where it gradually releases all allocated resources, such as modules and various critical internal structures. It also makes several calls to the [garbage collector](#). This can trigger the execution of code in user-defined destructors or weakref callbacks. Code executed during the shutdown phase can encounter various exceptions as the resources it relies on may not function anymore (common examples are library modules or the warnings machinery).

The main reason for interpreter shutdown is that the `__main__` module or the script being run has finished executing.

## iterable

An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as [list](#), [str](#), and [tuple](#)) and some non-sequence types like [dict](#), [file objects](#), and objects of any classes you define with

an `__iter__()` method or with a `__getitem__()` method that implements [sequence](#) semantics.

Iterables can be used in a `for` loop and in many other places where a sequence is needed (`zip()`, `map()`, ...). When an iterable object is passed as an argument to the built-in function `iter()`, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call `iter()` or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also [iterator](#), [sequence](#), and [generator](#).

## iterator

An object representing a stream of data. Repeated calls to the iterator's `__next__()` method (or passing it to the built-in function `next()`) return successive items in the stream. When no more data are available a `StopIteration` exception is raised instead. At this point, the iterator object is exhausted and any further calls to its `__next__()` method just raise `StopIteration` again. Iterators are required to have an `__iter__()` method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a `list`) produces a fresh new iterator each time you pass it to the `iter()` function or use it in a `for` loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in [Iterator Types](#).

**CPython implementation detail:** CPython does not consistently apply the requirement that an iterator define `__iter__()`.

## key function

A key function or collation function is a callable that returns

a value used for sorting or ordering. For example, `locale.strxfrm()` is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include `min()`, `max()`, `sorted()`, `list.sort()`, `heapq.merge()`, `heapq.nsmallest()`, `heapq.nlargest()`, and `itertools.groupby()`.

There are several ways to create a key function. For example, the `str.lower()` method can serve as a key function for case insensitive sorts. Alternatively, a key function can be built from a `lambda` expression such as `lambda r: (r[0], r[2])`. Also, `operator.attrgetter()`, `operator.itemgetter()`, and `operator.methodcaller()` are three key function constructors. See the [Sorting HOW TO](#) for examples of how to create and use key functions.

## keyword argument

See [argument](#).

## lambda

An anonymous inline function consisting of a single [expression](#) which is evaluated when the function is called. The syntax to create a lambda function is `lambda [parameters]: expression`

## LBYL

Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the [EAFP](#) approach and is characterized by the presence of many `if` statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, `if key in mapping: return mapping[key]` can fail if another thread removes `key` from `mapping` after the test, but before the lookup. This

issue can be solved with locks or by using the EAFP approach.

## locale encoding

On Unix, it is the encoding of the LC\_CTYPE locale. It can be set with `locale.setlocale(locale.LC_CTYPE, new_locale)`.

On Windows, it is the ANSI code page (ex: "cp1252").

On Android and VxWorks, Python uses "utf-8" as the locale encoding.

`locale.getencoding()` can be used to get the locale encoding.

See also the [filesystem encoding and error handler](#).

## list

A built-in Python [sequence](#). Despite its name it is more akin to an array in other languages than to a linked list since access to elements is  $O(1)$ .

## list comprehension

A compact way to process all or part of the elements in a sequence and return a list with the results. `result = [{'{:#04x}'.format(x) for x in range(256) if x % 2 == 0}]` generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The `if` clause is optional. If omitted, all elements in `range(256)` are processed.

## loader

An object that loads a module. It must define a method named `load_module()`. A loader is typically returned by a [finder](#). See [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/] for details and `importlib.abc.Loader` for an [abstract base class](#).

## magic method

An informal synonym for [special method](#).

## mapping

A container object that supports arbitrary key lookups and implements the methods specified in the `collections.abc.Mapping` or `collections.abc.MutableMapping` abstract base classes. Examples include `dict`, `collections.defaultdict`, `collections.OrderedDict` and `collections.Counter`.

## meta path finder

A `finder` returned by a search of `sys.meta_path`. Meta path finders are related to, but different from `path entry finders`.

See `importlib.abc.MetaPathFinder` for the methods that meta path finders implement.

## metaclass

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in [Metaclasses](#).

## method

A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first `argument` (which is usually called `self`). See [function](#) and [nested scope](#).

## method resolution order

Method Resolution Order is the order in which base classes are searched for a member during lookup. See [The Python 2.3](#)

**Method Resolution Order** [<https://www.python.org/download/releases/2.3/mro/>] for details of the algorithm used by the Python interpreter since the 2.3 release.

## module

An object that serves as an organizational unit of Python code. Modules have a namespace containing arbitrary Python objects. Modules are loaded into Python by the process of [importing](#).

See also [package](#).

## module spec

A namespace containing the import-related information used to load a module. An instance of [importlib.machinery.ModuleSpec](#).

## MRO

See [method resolution order](#).

## mutable

Mutable objects can change their value but keep their [id\(\)](#). See also [immutable](#).

## named tuple

The term “named tuple” applies to any type or class that inherits from tuple and whose indexable elements are also accessible using named attributes. The type or class may have other features as well.

Several built-in types are named tuples, including the values returned by [time.localtime\(\)](#) and [os.stat\(\)](#). Another example is [sys.float\\_info](#):

```
>>> sys.float_info[1]           # indexed a
1024
>>> sys.float_info.max_exp      # named fie
1024
>>> isinstance(sys.float_info, tuple)  # kind of t
```

True

Some named tuples are built-in types (such as the above examples). Alternatively, a named tuple can be created from a regular class definition that inherits from `tuple` and that defines named fields. Such a class can be written by hand or it can be created with the factory function `collections.namedtuple()`. The latter technique also adds some extra methods that may not be found in hand-written or built-in named tuples.

## namespace

The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions `builtins.open` and `os.open()` are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing `random.seed()` or `itertools.islice()` makes it clear that those functions are implemented by the `random` and `itertools` modules, respectively.

## namespace package

A [PEP 420](https://peps.python.org/pep-0420/) [https://peps.python.org/pep-0420/] `package` which serves only as a container for subpackages. Namespace packages may have no physical representation, and specifically are not like a `regular package` because they have no `__init__.py` file.

See also [module](#).

## nested scope

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables both read and write in the

innermost scope. Likewise, global variables read and write to the global namespace. The `nonlocal` allows writing to outer scopes.

## new-style class

Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python's newer, versatile features like `__slots__`, descriptors, properties, `__getattr__()`, class methods, and static methods.

## object

Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any [new-style class](#).

## package

A Python [module](#) which can contain submodules or recursively, subpackages. Technically, a package is a Python module with a `__path__` attribute.

See also [regular package](#) and [namespace package](#).

## parameter

A named entity in a [function](#) (or method) definition that specifies an [argument](#) (or in some cases, arguments) that the function can accept. There are five kinds of parameter:

- *positional-or-keyword*: specifies an argument that can be passed either [positionally](#) or as a [keyword argument](#). This is the default kind of parameter, for example *foo* and *bar* in the following:

```
def func(foo, bar=None): ...
```

- *positional-only*: specifies an argument that can be supplied only by position. Positional-only parameters can be defined by including a `/` character in the parameter list of the function definition after them, for example *posonly1* and *posonly2* in the following:

```
def func(posonly1, posonly2, /, positional_or_k
```

- *keyword-only*: specifies an argument that can be supplied only by keyword. Keyword-only parameters can be defined by including a single var-positional parameter or bare `*` in the parameter list of the function definition before them, for example *kw\_only1* and *kw\_only2* in the following:

```
def func(arg, *, kw_only1, kw_only2): ...
```

- *var-positional*: specifies that an arbitrary sequence of positional arguments can be provided (in addition to any positional arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `*`, for example *args* in the following:

```
def func(*args, **kwargs): ...
```

- *var-keyword*: specifies that arbitrarily many keyword arguments can be provided (in addition to any keyword arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `**`, for example *kwargs* in the example above.

Parameters can specify both optional and required arguments, as well as default values for some optional arguments.

See also the [argument](#) glossary entry, the FAQ question on [the difference between arguments and parameters](#), the [inspect.Parameter](#) class, the [Function definitions](#) section, and [PEP 362](#) [<https://peps.python.org/pep-0362/>].

## path entry

A single location on the [import path](#) which the [path based finder](#) consults to find modules for importing.

## path entry finder

A [finder](#) returned by a callable on [sys.path\\_hooks](#) (i.e. a

[path entry hook](#)) which knows how to locate modules given a [path entry](#).

See [importlib.abc.PathEntryFinder](#) for the methods that path entry finders implement.

## path entry hook

A callable on the `sys.path_hook` list which returns a [path entry finder](#) if it knows how to find modules on a specific [path entry](#).

## path based finder

One of the default [meta path finders](#) which searches an [import path](#) for modules.

## path-like object

An object representing a file system path. A path-like object is either a `str` or `bytes` object representing a path, or an object implementing the `os.PathLike` protocol. An object that supports the `os.PathLike` protocol can be converted to a `str` or `bytes` file system path by calling the `os.fspath()` function; `os.fsdecode()` and `os.fsencode()` can be used to guarantee a `str` or `bytes` result instead, respectively. Introduced by [PEP 519](#) [<https://peps.python.org/pep-0519/>].

## PEP

Python Enhancement Proposal. A PEP is a design document providing information to the Python community, or describing a new feature for Python or its processes or environment. PEPs should provide a concise technical specification and a rationale for proposed features.

PEPs are intended to be the primary mechanisms for proposing major new features, for collecting community input on an issue, and for documenting the design decisions that have gone into Python. The PEP author is responsible for building consensus within the community and documenting dissenting opinions.

See [PEP 1](https://peps.python.org/pep-0001/) [https://peps.python.org/pep-0001/].

## portion

A set of files in a single directory (possibly stored in a zip file) that contribute to a namespace package, as defined in [PEP 420](https://peps.python.org/pep-0420/) [https://peps.python.org/pep-0420/].

## positional argument

See [argument](#).

## provisional API

A provisional API is one which has been deliberately excluded from the standard library's backwards compatibility guarantees. While major changes to such interfaces are not expected, as long as they are marked provisional, backwards incompatible changes (up to and including removal of the interface) may occur if deemed necessary by core developers. Such changes will not be made gratuitously – they will occur only if serious fundamental flaws are uncovered that were missed prior to the inclusion of the API.

Even for provisional APIs, backwards incompatible changes are seen as a “solution of last resort” - every attempt will still be made to find a backwards compatible resolution to any identified problems.

This process allows the standard library to continue to evolve over time, without locking in problematic design errors for extended periods of time. See [PEP 411](https://peps.python.org/pep-0411/) [https://peps.python.org/pep-0411/] for more details.

## provisional package

See [provisional API](#).

## Python 3000

Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

## Pythonic

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a **for** statement. Many other languages don't have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```
for i in range(len(food)):  
    print(food[i])
```

As opposed to the cleaner, Pythonic method:

```
for piece in food:  
    print(piece)
```

## qualified name

A dotted name showing the “path” from a module’s global scope to a class, function or method defined in that module, as defined in **PEP 3155** [<https://peps.python.org/pep-3155/>]. For top-level functions and classes, the qualified name is the same as the object’s name:

```
>>> class C:  
...     class D:  
...         def meth(self):  
...             pass  
...  
>>> C.__qualname__  
'C'  
>>> C.D.__qualname__  
'C.D'  
>>> C.D.meth.__qualname__  
'C.D.meth'
```

When used to refer to modules, the *fully qualified name* means the entire dotted path to the module, including any parent packages, e.g. `email.mime.text`:

```
>>> import email.mime.text
>>> email.mime.text.__name__
'email.mime.text'
```

## reference count

The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Some objects are “immortal” and have reference counts that are never modified, and therefore the objects are never deallocated. Reference counting is generally not visible to Python code, but it is a key element of the [CPython](#) implementation. Programmers can call the [sys.getrefcount\(\)](#) function to return the reference count for a particular object.

## regular package

A traditional [package](#), such as a directory containing an `__init__.py` file.

See also [namespace package](#).

## `__slots__`

A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

## sequence

An [iterable](#) which supports efficient element access using integer indices via the `__getitem__()` special method and defines a `__len__()` method that returns the length of the sequence. Some built-in sequence types are [list](#), [str](#), [tuple](#), and [bytes](#). Note that [dict](#) also supports `__getitem__()` and `__len__()`, but is considered a mapping rather than a sequence because the lookups use arbitrary [immutable](#) keys rather than integers.

The `collections.abc.Sequence` abstract base class

defines a much richer interface that goes beyond just `__getitem__()` and `__len__()`, adding `count()`, `index()`, `__contains__()`, and `__reversed__()`. Types that implement this expanded interface can be registered explicitly using `register()`.

## set comprehension

A compact way to process all or part of the elements in an iterable and return a set with the results. `results = {c for c in 'abracadabra' if c not in 'abc'}` generates the set of strings `{'r', 'd'}`. See [Displays for lists, sets and dictionaries](#).

## single dispatch

A form of [generic function](#) dispatch where the implementation is chosen based on the type of a single argument.

## slice

An object usually containing a portion of a [sequence](#). A slice is created using the subscript notation, `[]` with colons between numbers when several are given, such as in `variable_name[1:3:5]`. The bracket (subscript) notation uses [slice](#) objects internally.

## special method

A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in [Special method names](#).

## statement

A statement is part of a suite (a “block” of code). A statement is either an [expression](#) or one of several constructs with a keyword, such as `if`, `while` or `for`.

## strong reference

In Python’s C API, a strong reference is a reference to an object which is owned by the code holding the reference. The

strong reference is taken by calling `Py_INCREF()` when the reference is created and released with `Py_DECREF()` when the reference is deleted.

The `Py_NewRef()` function can be used to create a strong reference to an object. Usually, the `Py_DECREF()` function must be called on the strong reference before exiting the scope of the strong reference, to avoid leaking one reference.

See also [borrowed reference](#).

## text encoding

A string in Python is a sequence of Unicode code points (in range `U+0000–U+10FFFF`). To store or transfer a string, it needs to be serialized as a sequence of bytes.

Serializing a string into a sequence of bytes is known as “encoding”, and recreating the string from the sequence of bytes is known as “decoding”.

There are a variety of different text serialization [codecs](#), which are collectively referred to as “text encodings”.

## text file

A [file object](#) able to read and write `str` objects. Often, a text file actually accesses a byte-oriented datastream and handles the [text encoding](#) automatically. Examples of text files are files opened in text mode (`'r'` or `'w'`), `sys.stdin`, `sys.stdout`, and instances of `io.StringIO`.

See also [binary file](#) for a file object able to read and write [bytes-like objects](#).

## triple-quoted string

A string which is bound by three instances of either a quotation mark (") or an apostrophe ('). While they don't provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the

continuation character, making them especially useful when writing docstrings.

## type

The type of a Python object determines what kind of object it is; every object has a type. An object's type is accessible as its `__class__` attribute or can be retrieved with `type(obj)`.

## type alias

A synonym for a type, created by assigning the type to an identifier.

Type aliases are useful for simplifying [type hints](#). For example:

```
def remove_gray_shades(  
    colors: list[tuple[int, int, int]]) -> list  
    pass
```

could be made more readable like this:

```
Color = tuple[int, int, int]  
  
def remove_gray_shades(colors: list[Color]) -> list  
    pass
```

See [typing](#) and [PEP 484](#) [<https://peps.python.org/pep-0484/>], which describe this functionality.

## type hint

An [annotation](#) that specifies the expected type for a variable, a class attribute, or a function parameter or return value.

Type hints are optional and are not enforced by Python but they are useful to static type analysis tools, and aid IDEs with code completion and refactoring.

Type hints of global variables, class attributes, and functions, but not local variables, can be accessed using `typing.get_type_hints()`.

See [typing](#) and [PEP 484](#) [https://peps.python.org/pep-0484/], which describe this functionality.

## universal newlines

A manner of interpreting text streams in which all of the following are recognized as ending a line: the Unix end-of-line convention `'\n'`, the Windows convention `'\r\n'`, and the old Macintosh convention `'\r'`. See [PEP 278](#) [https://peps.python.org/pep-0278/] and [PEP 3116](#) [https://peps.python.org/pep-3116/], as well as [bytes.splitlines\(\)](#) for an additional use.

## variable annotation

An [annotation](#) of a variable or a class attribute.

When annotating a variable or a class attribute, assignment is optional:

```
class C:
    field: 'annotation'
```

Variable annotations are usually used for [type hints](#): for example this variable is expected to take [int](#) values:

```
count: int = 0
```

Variable annotation syntax is explained in section [Annotated assignment statements](#).

See [function annotation](#), [PEP 484](#) [https://peps.python.org/pep-0484/] and [PEP 526](#) [https://peps.python.org/pep-0526/], which describe this functionality. Also see [Annotations Best Practices](#) for best practices on working with annotations.

## virtual environment

A cooperatively isolated runtime environment that allows Python users and applications to install and upgrade Python distribution packages without interfering with the behaviour of other Python applications running on the same system.

See also [venv](#).

## **virtual machine**

A computer defined entirely in software. Python's virtual machine executes the **bytecode** emitted by the bytecode compiler.

## **Zen of Python**

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing `"import this"` at the interactive prompt.

# About these documents

These documents are generated from [reStructuredText](https://docutils.sourceforge.io/rst.html) [https://docutils.sourceforge.io/rst.html] sources by [Sphinx](https://www.sphinx-doc.org/) [https://www.sphinx-doc.org/], a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain is an entirely volunteer effort, just like Python itself. If you want to contribute, please take a look at the [Dealing with Bugs](#) page for information on how to do so. New volunteers are always welcome!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the [Docutils](https://docutils.sourceforge.io/) [https://docutils.sourceforge.io/] project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.

## Contributors to the Python Documentation

Many people have contributed to the Python language, the Python standard library, and the Python documentation. See [Misc/ACKS](https://github.com/python/cpython/tree/3.12/Misc/ACKS) [https://github.com/python/cpython/tree/3.12/Misc/ACKS] in the Python source distribution for a partial list of contributors.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!

# Dealing with Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.

It can be sometimes faster to fix bugs yourself and contribute patches to Python as it streamlines the process and involves less people. Learn how to [contribute](#).

## Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please submit a bug report on the [tracker](#). If you have a suggestion on how to fix it, include that as well.

You can also open a discussion item on our [Documentation Discourse forum](#) [<https://discuss.python.org/c/documentation/26>].

If you're short on time, you can also email documentation bug reports to [docs@python.org](mailto:docs@python.org) (behavioral bugs can be sent to [python-list@python.org](mailto:python-list@python.org)). 'docs@' is a mailing list run by volunteers; your request will be noticed, though it may take a while to be processed.

**Documentation Translations** [<https://devguide.python.org/documenting/#translating>]

A list of GitHub pages for documentation translation and their primary contacts.

## Using the Python issue tracker

Issue reports for Python itself should be submitted via the GitHub issues tracker (<https://github.com/python/cpython/issues>). The GitHub issues tracker offers a web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers' time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the tracker using the search box at the top of the page.

If the problem you're reporting is not already in the list, log in to GitHub. If you don't already have a GitHub account, create a new account using the "Sign up" link. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit an issue. Click on the "New issue" button in the top bar to report a new issue.

The submission form has two fields, "Title" and "Comment".

For the "Title" field, enter a *very* short description of the problem; fewer than ten words is good.

In the "Comment" field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to

include whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

Each issue report will be reviewed by a developer who will determine what needs to be done to correct the problem. You will receive an update each time an action is taken on the issue.

### See also

**How to Report Bugs Effectively** [<https://www.chiark.greenend.org.uk/~sgtatham/bugs.html>]

Article which goes into some detail about how to create a useful bug report. This describes what kind of information is useful and why it is useful.

**Bug Writing Guidelines** [<https://bugzilla.mozilla.org/page.cgi?id=bug-writing.html>]

Information about writing a good bug report. Some of this is specific to the Mozilla project, but describes general good practices.

## Getting started contributing to Python yourself

Beyond just reporting bugs that you find, you are also welcome to submit patches to fix them. You can find more information on how to get started patching Python in the [Python Developer's Guide](https://devguide.python.org/) [<https://devguide.python.org/>]. If you have questions, the [core-mentorship mailing list](https://mail.python.org/mailman3/lists/core-mentorship.python.org/) [<https://mail.python.org/mailman3/lists/core-mentorship.python.org/>] is a friendly place to get answers to any and all questions pertaining to the process of fixing issues in Python.

# History and License

## History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see <https://www.cwi.nl/>) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see <https://www.cnri.reston.va.us/>) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see <https://www.zope.org/>). In 2001, the Python Software Foundation (PSF, see <https://www.python.org/psf/>) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see <https://opensource.org/> for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

### ~~GPL-compatible?~~

---

~~0.9.0~~ 1991.2

---

~~0.9.1~~ 1995.2

---

~~0.9.2~~

---

~~0.9.3~~ BeOpen.com

---

~~0.9.4~~ CNRI

---

~~0.9.5~~ 1.6.1

---

~~Python~~ 1.6.1

~~Python~~ 2.0.1

~~Python~~ 2

~~Python~~ 3

~~Python~~ and above

## Note

GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

## Terms and conditions for accessing or otherwise using Python

Python software and documentation are licensed under the [PSF License Agreement](#).

Starting with Python 3.8.6, examples, recipes, and other code in the documentation are dual licensed under the PSF License Agreement and the [Zero-Clause BSD license](#).

Some software incorporated into Python is under different licenses. The licenses are listed with code falling under that license. See [Licenses and Acknowledgements for Incorporated Software](#) for an incomplete list of these licenses.

## PSF LICENSE AGREEMENT FOR PYTHON 3.12.0

1. This LICENSE AGREEMENT is between the Python Software the Individual or Organization ("Licensee") accessing 3.12.0 software in source or binary form and its asso

2. Subject to the terms and conditions of this License A grants Licensee a nonexclusive, royalty-free, world-w analyze, test, perform and/or display publicly, prepa distribute, and otherwise use Python 3.12.0 alone or version, provided, however, that PSF's License Agree copyright, i.e., "Copyright © 2001–2023 Python Softwa Reserved" are retained in Python 3.12.0 alone or in a prepared by Licensee.
3. In the event Licensee prepares a derivative work that incorporates Python 3.12.0 or any part thereof, and w derivative work available to others as provided herei agrees to include in any such work a brief summary of 3.12.0.
4. PSF is making Python 3.12.0 available to Licensee on PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS C EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAI WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTIC USE OF PYTHON 3.12.0 WILL NOT INFRINGE ANY THIRD PART
5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USER FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 3. THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate u its terms and conditions.
7. Nothing in this License Agreement shall be deemed to of agency, partnership, or joint venture between PSF Agreement does not grant permission to use PSF tradem trademark sense to endorse or promote products or ser third party.
8. By copying, installing or otherwise using Python 3.12 to be bound by the terms and conditions of this Licer

# BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

## BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen", 160 Saratoga Avenue, Santa Clara, CA 95051, and the Licensee ("Licensee") accessing and otherwise using this software in source code form and its associated documentation ("the Software").
2. Subject to the terms and conditions of this BeOpen Python License, BeOpen hereby grants Licensee a non-exclusive, royalty-free license to reproduce, analyze, test, perform and/or display publicly, to make works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License Software, alone or in any derivative version prepared by Licensee, bears the following text in prominent locations: "BeOpen Python License Software, Copyright (c) 1998 BeOpen.com. All Rights Reserved." and "BeOpen Python License Software, Copyright (c) 1998 BeOpen.com. All Rights Reserved.".
3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED, BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE. THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
5. This License Agreement will automatically terminate upon the use of the Software without its terms and conditions.
6. This License Agreement shall be governed by and interpreted in accordance with the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to constitute an agency, partnership, or joint venture between BeOpen and Licensee. This Agreement does not grant permission to use BeOpen trademarks in a trademark sense to endorse or promote products or services of a third party. As an exception, the "BeOpen Python" logo located at <http://www.pythonlabs.com/logos.html> may be used according to the terms and conditions of the BeOpen Python License Software.

granted on that web page.

7. By copying, installing or otherwise using the software, you are bound by the terms and conditions of this License Agreement.

## **CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1**

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") wishing to use Python 1.6.1 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, CNRI grants Licensee a nonexclusive, royalty-free, world-wide license to copy, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in combination with other provided, however, that CNRI's License Agreement and the text of the License, i.e., "Copyright © 1995-2001 Corporation for National Research Initiatives. All Rights Reserved" are retained in Python 1.6.1 alone or in combination with other prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the name of the Licensee) which is made available subject to the terms and conditions of the License Agreement. This Agreement together with Python 1.6.1 software shall be made available on the internet using the following unique, persistent identifier: 1895.22/1013. This Agreement may also be obtained from CNRI on the internet using the following URL: <http://hdl.handle.net/1895.22/1013>.
3. In the event Licensee prepares a derivative work that incorporates Python 1.6.1 or any part thereof, and makes such work available to others as provided herein, then Licensee must include in any such work a brief summary of the changes made.
4. CNRI is making Python 1.6.1 available to Licensee on an "AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO, WARRANTIES OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USER FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1 THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate upon the expiration of its terms and conditions.
7. This License Agreement shall be governed by the federal law of the United States, including without limitation federal law, and, to the extent such U.S. federal law does not apply, the law of the Commonwealth of Virginia, excluding Virginia's conflict of laws provisions. Notwithstanding the foregoing, with regard to derivative works of Python 1.6.1 that incorporate non-separable material that was developed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to such derivative works. With respect to Paragraphs 4, 5, and 7 of this License Agreement, this License Agreement shall be deemed to create no partnership, joint venture, or other business relationship between CNRI and Licensee, and does not grant permission to use CNRI trademarks or trade names, nor does it give Licensee the right to endorse or promote products or services of CNRI or any other party.
8. By clicking on the "ACCEPT" button where indicated, or by otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

## **CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2**

Copyright © 1991 - 1995, Stichting Mathematisch Centrum  
Amsterdam, The Netherlands. All rights reserved.

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that this permission notice and this permission notice appear in supporting documentation.

notice appear in the supporting documentation, and that the name of neither A

Bioreason or Mojam Media be used in advertising or public distribution of the software without specific, written permission.

## UUencode and UUdecode functions

The `uu` module contains the following notice:

Copyright 1994 by Lance Ellinghouse  
Cathedral City, California Republic, United States of America  
All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies, and that both that copyright notice and this permission notice appear in all supporting documentation, and that the name of Lance Ellinghouse not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission. LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:

- Use `binascii` module to do the actual line-by-line conversion between `ascii` and `binary`. This results in a 1000-fold speedup. The version is still 5 times faster, though.
- Arguments more compliant with Python standard

## XML Remote Procedure Calls

The `xmlrpc.client` module contains the following notice:

The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB  
Copyright (c) 1999-2002 by Fredrik Lundh

By obtaining, using, and/or copying this software and/or associated documentation, you agree that you have read, and will comply with the following terms and conditions:

Permission to use, copy, modify, and distribute this software and its associated documentation for any purpose and without restriction is hereby granted, provided that the above copyright notice appear in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Secret Labs AB or the author not be used in advertising or promotional materials pertaining to distribution of the software without specific prior permission.

SECRET LABS AB AND THE AUTHOR DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. Jean-Philippe Aumasson (https://131002.net/siphhash/siphhash24/little)
```

## strtod and dtoa

The file `Python/dtoa.c`, which supplies C functions `dtoa` and `strtod` for conversion of C doubles to and from strings, is derived from the file of the same name by David M. Gay, currently available from <https://web.archive.org/web/20220517033456/http://www.netlib.org/fp/dtoa.c>. The original file, as retrieved on March 16, 2009, contains the following copyright and licensing notice:

```
/* *****
 *
 * The author of this software is David M. Gay.

## OpenSSL

The modules `hashlib`, `posix`, `ssl`, `crypt` use the OpenSSL library for added performance if made available by the operating system. Additionally, the Windows and macOS installers for Python may include a copy of the OpenSSL libraries, so we include a copy of the OpenSSL license here. For the OpenSSL 3.0 release, and later releases derived from that, the Apache License v2 applies:

Apache License  
Version 2.0, January 2004  
<https://www.apache.org/licenses/>

TERMS AND CONDITIONS FOR USE, REPRODUCTION, AND DISTRIBUTION

### 1. Definitions.

"License" shall mean the terms and conditions for use and distribution as defined by Sections 1 through 9 of this License.

"Licensor" shall mean the copyright owner or entity authorized by the copyright owner that is granting the License.

"Legal Entity" shall mean the union of the acting entity and all other entities that are part of the same legal entity, including its successors and assigns.

other entities that control, are controlled by, or are under common control with that entity. For the purposes of this definition, "control" means (i) the power, direct or indirect, to exercise direction or management of such entity, whether by contract or otherwise, or (ii) ownership of fifty percent (50%) or more of its outstanding shares, or (iii) beneficial ownership of such entity.

"You" (or "Your") shall mean an individual or Legal Entity exercising permissions granted by this License.

"Source" form shall mean the preferred form for making modifications, including but not limited to software source code, documentation source, and configuration files.

"Object" form shall mean any form resulting from mechanical transformation or translation of a Source form, including but not limited to compiled object code, generated documentation, and conversions to other media types.

"Work" shall mean the work of authorship, whether in Source or Object form, made available under the License, as indicated by a copyright notice that is included in or attached to the work (an example is provided in the Appendix below).

"Derivative Works" shall mean any work, whether in Source or Object form, that is based on (or derived from) the Work and/or its editorial revisions, annotations, elaborations, or other modifications which represent, as a whole, an original work of authorship. For purposes of this License, Derivative Works shall not include works that are separable from, or merely link (or bind by name) to the Work and Derivative Works thereof.

"Contribution" shall mean any work of authorship, including the original version of the Work and any modifications or additions to that Work or Derivative Works thereof, that is intentionally submitted to Licensor for inclusion in the Work by the copyright owner, or by an individual or Legal Entity authorized to submit on its behalf. For the purposes of this definition,

means any form of electronic, verbal, or written communication to the Licensor or its representatives, including but not limited to communication on electronic mailing lists, source code control and issue tracking systems that are managed by, or on behalf of, the Licensor for the purpose of discussing and improving the Work, but excluding communication that is conspicuously marked or otherwise designated in writing by the copyright owner as "Not for Distribution."

"Contributor" shall mean Licensor and any individual or entity, on behalf of whom a Contribution has been received by Licensor or subsequently incorporated within the Work.

2. **Grant of Copyright License.** Subject to the terms and conditions of this License, each Contributor hereby grants to You a copyright license to reproduce, prepare Derivative Works of, publicly display, publicly perform, sublicense, and distribute the Work and such Derivative Works in Source or Object form.
3. **Grant of Patent License.** Subject to the terms and conditions of this License, each Contributor hereby grants to You a copyright license to reproduce, prepare Derivative Works of, publicly display, publicly perform, sublicense, and distribute the Work and such Derivative Works in Source or Object form, and a non-exclusive, non-transferable, non-sublicensable, non-assignable, worldwide, non-exclusive, no-charge, royalty-free, irrevocable and exclusive (except as stated in this section) patent license to make, have made, use, offer to sell, sell, import, and otherwise transfer the Work, where such license applies only to those patent claims asserted by such Contributor that are necessarily infringed by their Contribution(s) alone or by combination of their Contribution(s) with the Work to which such Contribution(s) was submitted. If You institute patent litigation against any entity (including a Contributor) alleging that the Work or a Contribution incorporated within the Work constitutes or contributory patent infringement, then any patent licenses granted to You under this License for that Work shall terminate as of the date such litigation is filed.
4. **Redistribution.** You may reproduce and distribute copies of the Work or Derivative Works thereof in any medium, with or without modifications, and in Source or Object form, provided that

meet the following conditions:

- (a) You must give any other recipients of the Work or  
Derivative Works a copy of this License; and
- (b) You must cause any modified files to carry prominent  
notices stating that You changed the files; and
- (c) You must retain, in the Source form of any Derivative  
Works that You distribute, all copyright, patent, trademark,  
and attribution notices from the Source form of the Work,  
excluding those notices that do not pertain to any part of  
the Derivative Works; and
- (d) If the Work includes a "NOTICE" text file as part of  
its distribution, then any Derivative Works that You  
distribute must include a readable copy of the attribution  
notices contained within such NOTICE file, excluding those  
notices that pertain to any part of the Derivative Works, in  
at least one of the following places: within a NOTICE text  
file distributed as part of the Derivative Works; within the  
Source form documentation, if provided along with the  
Derivative Works; within a display generated by the  
Derivative Works; wherever such third-party notices normally  
appear in the Derivative Works; or on the media used to  
distribute the Derivative Works. You may add Your own  
attribution notices within Derivative Works that You  
distribute, or as an addendum to the NOTICE text from the  
Work, provided that such additional attribution notices cannot  
be construed as modifying the License.

You may add Your own copyright statement to Your modified  
version of the Work, but you must provide the same copyright  
statement to all recipients of the Work or Derivative Works  
for use, reproduction, or distribution of Your modified  
version. You may also make a separate arrangement for  
reproduction, and distribution of the Work otherwise than  
under the conditions stated in this License.

5. Submission of Contributions. Unless You explicitly state otherwise, any Contribution intentionally submitted for inclusion in the Work by You to the Licensor shall be under the terms and conditions of this License, without any additional terms or conditions. Notwithstanding the above, nothing herein shall supersede or modify the terms of any separate license agreement you may have entered into with Licensor regarding such Contributions.
6. Trademarks. This License does not grant permission to use the names, trademarks, service marks, or product names of the Licensor, except as required for reasonable and customary use in identifying the origin of the Work and reproducing the content of the Work.
7. Disclaimer of Warranty. Unless required by applicable law or agreed to in writing, Licensor provides the Work (and any Contributions) on an "AS IS" BASIS, WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied, including, without limitation, any warranties or conditions of TITLE, NON-INFRINGEMENT, MERCHANTABILITY, or FITNESS FOR A PARTICULAR PURPOSE. You are solely responsible for determining the appropriateness of using or redistributing the Work and assume any risks associated with Your exercise of permissions under this License.
8. Limitation of Liability. In no event and under no legal theory, whether in tort (including negligence), contract, or otherwise, shall the Licensor be liable to You for damages, including any direct, indirect, incidental, or consequential damages of any character arising as a result of this License or out of the use or inability to use the Work (including but not limited to damages for loss of profits, work stoppage, computer failure or malfunction, or any other commercial damages or losses), even if such Contributor has been advised of the possibility of such damages.
9. Accepting Warranty or Additional Liability. While redistributing the Work or Derivative Works thereof, You may choose to offer, accept, or charge a fee for, acceptance of support, warranty, indemnification, or other liability obligations (excluding any obligation for damages already provided under this License) to any person who exercises the rights granted to You by this License.

or other liability obligations and/or rights consist of the License. However, in accepting such obligations, You shall do so on Your own behalf and on Your sole responsibility, not on behalf of any other Contributor, and only if You agree to indemnify, defend, and hold each Contributor harmless for any liability incurred by, or claims asserted against, such Contributor by or for your accepting any such warranty or additional liability.

END OF TERMS AND CONDITIONS

## expat

The [pyexpat](#) extension is built using an included copy of the expat sources unless the build is configured `--with-system-expat`:

*Future statement definitions*

[\\_\\_main\\_\\_](#)

*The environment where top-level code is run. Covers command-line interfaces, import-time behavior, and*  
``\_name\_`` =  
'\_main\_'.

[\\_thread](#)

*Low-level threading API.*

## [a](#)

[abc](#)

*Abstract base classes according to :pep:`3119`.*

[aifc](#)

**Deprecated:** *Read and write audio files in AIFF or AIFC format.*

[argparse](#)

*Command-line option and argument parsing library.*

[array](#)

*Space efficient arrays of uniformly typed numeric values.*

[ast](#)

*Abstract Syntax Tree classes and manipulation.*

[asyncio](#)

*Asynchronous I/O.*

[atexit](#)

*Register and execute cleanup functions.*

[audioop](#)

**Deprecated:**

*Manipulate raw audio data.*

## **b**

**base64**

*RFC 4648: Base16, Base32, Base64 Data Encodings; Base85 and Ascii85*

**bdb**

*Debugger framework.*

**binascii**

*Tools for converting between binary and various ASCII-encoded binary representations.*

**bisect**

*Array bisection algorithms for binary searching.*

**builtins**

*The module that provides the built-in namespace.*

**bz2**

*Interfaces for bzip2 compression and decompression.*

## **c**

**calendar**

*Functions for working with calendars, including some emulation of the Unix cal program.*

**cgi**

**Deprecated:** *Helpers for running Python scripts via the Common Gateway Interface.*

**cgitb**

**Deprecated:** *Configurable traceback handler for CGI scripts.*

**chunk**

**Deprecated:** *Module to read IFF chunks.*

**cmath**

*Mathematical functions for complex numbers.*

<code>cmd</code>	Build line-oriented command interpreters.
<code>code</code>	Facilities to implement read-eval-print loops.
<code>codecs</code>	Encode and decode data and streams.
<code>codeop</code>	Compile (possibly incomplete) Python code.
<code>collections</code>	Container datatypes
<code>collections.abc</code>	Abstract base classes for containers
<code>colorsys</code>	Conversion functions between RGB and other color systems.
<code>compileall</code>	Tools for byte-compiling all Python source files in a directory tree.
<code>concurrent</code>	
<code>concurrent.futures</code>	Execute computations concurrently using threads or processes.
<code>configparser</code>	Configuration file parser.
<code>contextlib</code>	Utilities for with-statement contexts.
<code>contextvars</code>	Context Variables
<code>copy</code>	Shallow and deep copy operations.
<code>copyreg</code>	Register pickle support functions.
<code>cProfile</code>	
<code>crypt</code> (Unix)	<b>Deprecated:</b> The <code>crypt()</code> function used to check Unix passwords.
<code>csv</code>	Write and read tabular data to and from delimited files.
<code>ctypes</code>	A foreign function library for Python.

<code>curses</code> (Unix)	An interface to the curses library, providing portable terminal handling.
<code>curses.ascii</code>	Constants and set-membership functions for ASCII characters.
<code>curses.panel</code>	A panel stack extension that adds depth to curses windows.
<code>curses.textpad</code>	Emacs-like input editing in a curses window.

## d

<code>dataclasses</code>	Generate special methods on user-defined classes.
<code>datetime</code>	Basic date and time types.
<code>dbm</code>	Interfaces to various Unix "database" formats.
<code>dbm.dumb</code>	Portable implementation of the simple DBM interface.
<code>dbm.gnu</code> (Unix)	GNU's reinterpretation of dbm.
<code>dbm.ndbm</code> (Unix)	The standard "database" interface, based on ndbm.
<code>decimal</code>	Implementation of the General Decimal Arithmetic Specification.
<code>difflib</code>	Helpers for computing differences between objects.
<code>dis</code>	Disassembler for Python bytecode.
<code>doctest</code>	Test pieces of code

*within docstrings.*

## **e**

<b>email</b>	<i>Package supporting the parsing, manipulating, and generating email messages.</i>
<b>email.charset</b>	<i>Character Sets Storing and Retrieving</i>
<b>email.contentmanager</b>	<i>Content from MIME Parts</i>
<b>email.encoders</b>	<i>Encoders for email message payloads.</i>
<b>email.errors</b>	<i>The exception classes used by the email package.</i>
<b>email.generator</b>	<i>Generate flat text email messages from a message structure.</i>
<b>email.header</b>	<i>Representing non-ASCII headers</i>
<b>email.headerregistry</b>	<i>Automatic Parsing of headers based on the field name</i>
<b>email.iterators</b>	<i>Iterate over a message object tree.</i>
<b>email.message</b>	<i>The base class representing email messages.</i>
<b>email.mime</b>	<i>Build MIME messages.</i>
<b>email.parser</b>	<i>Parse flat text email messages to produce a message object structure.</i>
<b>email.policy</b>	<i>Controlling the parsing and generating of messages</i>
<b>email.utils</b>	<i>Miscellaneous email package utilities.</i>
<b>encodings</b>	

<code>encodings.idna</code>	Internationalized Domain Names implementation
<code>encodings.mbcs</code>	Windows ANSI codepage
<code>encodings.utf_8_sig</code>	UTF-8 codec with BOM signature
<code>ensurepip</code>	Bootstrapping the "pip" installer into an existing Python installation or virtual environment.
<code>enum</code>	Implementation of an enumeration class.
<code>errno</code>	Standard errno system symbols.

## f

<code>faulthandler</code>	Dump the Python traceback.
<code>fcntl</code> (Unix)	The <code>fcntl()</code> and <code>ioctl()</code> system calls.
<code>filecmp</code>	Compare files efficiently.
<code>fileinput</code>	Loop over standard input or a list of files.
<code>fnmatch</code>	Unix shell style filename pattern matching.
<code>fractions</code>	Rational numbers.
<code>ftplib</code>	FTP protocol client (requires sockets).
<code>functools</code>	Higher-order functions and operations on callable objects.

## g

<code>gc</code>	Interface to the cycle-detecting garbage collector.
<code>getopt</code>	Portable parser for

	<i>command line options; support both short and long option names.</i>
<b>getpass</b>	<i>Portable reading of passwords and retrieval of the userid.</i>
<b>gettext</b>	<i>Multilingual internationalization services.</i>
<b>glob</b>	<i>Unix shell style pathname pattern expansion.</i>
<b>graphlib</b>	<i>Functionality to operate with graph-like structures</i>
<b>grp (Unix)</b>	<i>The group database (getgrnam() and friends).</i>
<b>gzip</b>	<i>Interfaces for gzip compression and decompression using file objects.</i>

## **h**

<b>hashlib</b>	<i>Secure hash and message digest algorithms.</i>
<b>heapq</b>	<i>Heap queue algorithm (a.k.a. priority queue).</i>
<b>hmac</b>	<i>Keyed-Hashing for Message Authentication (HMAC) implementation</i>
<b>html</b>	<i>Helpers for manipulating HTML.</i>
<b>html.entities</b>	<i>Definitions of HTML general entities.</i>
<b>html.parser</b>	<i>A simple parser that can handle HTML and XHTML.</i>

<code>http</code>	HTTP status codes and messages
<code>http.client</code>	HTTP and HTTPS protocol client (requires sockets).
<code>http.cookiejar</code>	Classes for automatic handling of HTTP cookies.
<code>http.cookies</code>	Support for HTTP state management (cookies).
<code>http.server</code>	HTTP server and request handlers.

## i

<code>idlelib</code>	Implementation package for the IDLE shell/editor.
<code>imaplib</code>	IMAP4 protocol client (requires sockets).
<code>imghdr</code>	<b>Deprecated:</b> Determine the type of image contained in a file or byte stream.
<code>importlib</code>	The implementation of the import machinery.
<code>importlib.abc</code>	Abstract base classes related to import
<code>importlib.machinery</code>	Importers and path hooks
<code>importlib.metadata</code>	Accessing package metadata
<code>importlib.resources</code>	Package resource reading, opening, and access
<code>importlib.resources.abc</code>	Abstract base classes for resources
<code>importlib.util</code>	Utility code for importers
<code>inspect</code>	Extract information and source code from live

<code>io</code>	<i>objects.</i>
<code>ipaddress</code>	<i>Core tools for working with streams.</i>
<code>itertools</code>	<i>IPv4/IPv6 manipulation library.</i>
	<i>Functions creating iterators for efficient looping.</i>

<b>j</b>	
<code>json</code>	<i>Encode and decode the JSON format.</i>
<code>json.tool</code>	<i>A command line to validate and pretty-print JSON.</i>

<b>k</b>	
<code>keyword</code>	<i>Test whether a string is a keyword in Python.</i>

<b>l</b>	
<code>lib2to3</code>	<i>The 2to3 library</i>
<code>linecache</code>	<i>Provides random access to individual lines from text files.</i>
<code>locale</code>	<i>Internationalization services.</i>
<code>logging</code>	<i>Flexible event logging system for applications.</i>
<code>logging.config</code>	<i>Configuration of the logging module.</i>
<code>logging.handlers</code>	<i>Handlers for the logging module.</i>
<code>lzma</code>	<i>A Python wrapper for the liblzma compression library.</i>

<b>m</b>	
<code>mailbox</code>	<i>Manipulate mailboxes in various formats</i>

<code>mailcap</code>	<b>Deprecated:</b> Mailcap file handling.
<code>marshal</code>	Convert Python objects to streams of bytes and back (with different constraints).
<code>math</code>	Mathematical functions ( <code>sin()</code> etc.).
<code>mimetypes</code>	Mapping of filename extensions to MIME types.
<code>mmap</code>	Interface to memory-mapped files for Unix and Windows.
<code>modulefinder</code>	Find modules used by a script.
<code>msilib</code> (Windows)	<b>Deprecated:</b> Creation of Microsoft Installer files, and CAB files.
<code>msvcrt</code> (Windows)	Miscellaneous useful routines from the MS VC++ runtime.
<code>multiprocessing</code>	Process-based parallelism.
<code>multiprocessing.connection</code>	API for dealing with sockets.
<code>multiprocessing.dummy</code>	Dumb wrapper around threading.
<code>multiprocessing.managers</code>	Share data between processes with shared objects.
<code>multiprocessing.pool</code>	Create pools of processes.
<code>multiprocessing.shared_memory</code>	Provides shared memory for direct access across processes.
<code>multiprocessing.sharedctypes</code>	Allocate ctypes objects from shared memory.

<code>netrc</code>	Loading of <code>.netrc</code> files.
<code>nis</code> (Unix)	<b>Deprecated:</b> Interface to Sun's NIS (Yellow Pages) library.
<code>nntplib</code>	<b>Deprecated:</b> NNTP protocol client (requires sockets).
<code>numbers</code>	Numeric abstract base classes (Complex, Real, Integral, etc.).

## **o**

<code>operator</code>	Functions corresponding to the standard operators.
<code>optparse</code>	<b>Deprecated:</b> Command-line option parsing library.
<code>os</code>	Miscellaneous operating system interfaces.
<code>os.path</code>	Operations on pathnames.
<code>ossaudiodev</code> (Linux, FreeBSD)	<b>Deprecated:</b> Access to OSS-compatible audio devices.

## **p**

<code>pathlib</code>	Object-oriented filesystem paths
<code>pdb</code>	The Python debugger for interactive interpreters.
<code>pickle</code>	Convert Python objects to streams of bytes and back.
<code>pickletools</code>	Contains extensive comments about the pickle protocols and pickle-machine opcodes, as well as some useful

<code>pipes</code> (Unix)	<i>functions.</i> <b>Deprecated:</b> A Python interface to Unix shell pipelines.
<code>pkgutil</code>	<i>Utilities for the import system.</i>
<code>platform</code>	<i>Retrieves as much platform identifying data as possible.</i>
<code>plistlib</code>	<i>Generate and parse Apple plist files.</i>
<code>poplib</code>	<i>POP3 protocol client (requires sockets).</i>
<code>posix</code> (Unix)	<i>The most common POSIX system calls (normally used via module <code>os</code>).</i>
<code>pprint</code>	<i>Data pretty printer.</i>
<code>profile</code>	<i>Python source profiler.</i>
<code>pstats</code>	<i>Statistics object for use with the profiler.</i>
<code>pty</code> (Unix)	<i>Pseudo-Terminal Handling for Unix.</i>
<code>pwd</code> (Unix)	<i>The password database (getpwnam() and friends).</i>
<code>py_compile</code>	<i>Generate byte-code files from Python source files.</i>
<code>pyclbr</code>	<i>Supports information extraction for a Python module browser.</i>
<code>pydoc</code>	<i>Documentation generator and online help system.</i>

## q

<code>queue</code>	<i>A synchronized queue class.</i>
<code>quopri</code>	<i>Encode and decode files</i>

*using the MIME quoted-printable encoding.*

## **r**

<b>random</b>	<i>Generate pseudo-random numbers with various common distributions.</i>
<b>re</b>	<i>Regular expression operations.</i>
<b>readline</b> (Unix)	<i>GNU readline support for Python.</i>
<b>reprlib</b>	<i>Alternate repr() implementation with size limits.</i>
<b>resource</b> (Unix)	<i>An interface to provide resource usage information on the current process.</i>
<b>rlcompleter</b>	<i>Python identifier completion, suitable for the GNU readline library.</i>
<b>runpy</b>	<i>Locate and run Python modules without importing them first.</i>

## **s**

<b>sched</b>	<i>General purpose event scheduler.</i>
<b>secrets</b>	<i>Generate secure random numbers for managing secrets.</i>
<b>select</b>	<i>Wait for I/O completion on multiple streams.</i>
<b>selectors</b>	<i>High-level I/O multiplexing.</i>
<b>shelve</b>	<i>Python object persistence.</i>
<b>shlex</b>	<i>Simple lexical analysis</i>

<code>shutil</code>	<i>for Unix shell-like languages.</i> <i>High-level file operations, including copying.</i>
<code>signal</code>	<i>Set handlers for asynchronous events.</i>
<code>site</code>	<i>Module responsible for site-specific configuration.</i>
<code>sitecustomize</code>	
<code>smtplib</code>	<i>SMTP protocol client (requires sockets).</i>
<code>sndhdr</code>	<b>Deprecated:</b> <i>Determine type of a sound file.</i>
<code>socket</code>	<i>Low-level networking interface.</i>
<code>socketserver</code>	<i>A framework for network servers.</i>
<code>spwd</code> (Unix)	<b>Deprecated:</b> <i>The shadow password database (getspnam() and friends).</i>
<code>sqlite3</code>	<i>A DB-API 2.0 implementation using SQLite 3.x.</i>
<code>ssl</code>	<i>TLS/SSL wrapper for socket objects</i>
<code>stat</code>	<i>Utilities for interpreting the results of os.stat(), os.lstat() and os.fstat().</i>
<code>statistics</code>	<i>Mathematical statistics functions</i>
<code>string</code>	<i>Common string operations.</i>
<code>stringprep</code>	<i>String preparation, as per RFC 3453</i>
<code>struct</code>	<i>Interpret bytes as packed binary data.</i>

<code>subprocess</code>	Subprocess management.
<code>sunau</code>	<b>Deprecated:</b> Provide an interface to the Sun AU sound format.
<code>symtable</code>	Interface to the compiler's internal symbol tables.
<code>sys</code>	Access system-specific parameters and functions.
<code>sys.monitoring</code>	Access and control event monitoring
<code>sysconfig</code>	Python's configuration information
<code>syslog</code> (Unix)	An interface to the Unix syslog library routines.

## t

<code>tabnanny</code>	Tool for detecting white space related problems in Python source files in a directory tree.
<code>tarfile</code>	Read and write tar-format archive files.
<code>telnetlib</code>	<b>Deprecated:</b> Telnet client class.
<code>tempfile</code>	Generate temporary files and directories.
<code>termios</code> (Unix)	POSIX style tty control.
<code>test</code>	Regression tests package containing the testing suite for Python.
<code>test.support</code>	Support for Python's regression test suite.
<code>test.support.bytecode</code>	Support tools for testing correct bytecode generation.
<code>test.support.import_helper</code>	Support for import tests.

	Support for os tests.
<code>test.support.os_helper</code>	
	Support for Python's script execution tests.
<code>test.support.script_helper</code>	
	Support for socket tests.
<code>test.support.socket_helper</code>	
	Support for threading tests.
<code>test.support.threading_helper</code>	
	Support for warnings tests.
<code>test.support.warnings_helper</code>	
<code>textwrap</code>	Text wrapping and filling
<code>threading</code>	Thread-based parallelism.
<code>time</code>	Time access and conversions.
<code>timeit</code>	Measure the execution time of small code snippets.
<code>tkinter</code>	Interface to Tcl/Tk for graphical user interfaces
	Color choosing dialog
<code>tkinter.colorchooser</code>	
<code>(Tk)</code>	
	Tkinter base class for dialogs
<code>tkinter.commondialog</code>	
<code>(Tk)</code>	
<code>tkinter.dnd</code>	Tkinter drag-and-drop interface
<code>(Tk)</code>	
	Dialog classes for file selection
<code>tkinter.filedialog</code>	
<code>(Tk)</code>	
<code>tkinter.font</code>	Tkinter font-wrapping class
<code>(Tk)</code>	
	Various types of alert dialogs
<code>tkinter.messagebox</code>	
<code>(Tk)</code>	
	Text widget with a vertical scroll bar.
<code>tkinter.scrolledtext</code>	
<code>(Tk)</code>	

## *Simple dialog windows*

`tkinter.simpdialog`

*(Tk)*

<code>tkinter.tix</code>	<i>Tk Extension Widgets for Tkinter</i>
<code>tkinter.ttk</code>	<i>Tk themed widget set</i>
<code>token</code>	<i>Constants representing terminal nodes of the parse tree.</i>
<code>tokenize</code>	<i>Lexical scanner for Python source code.</i>
<code>tomllib</code>	<i>Parse TOML files.</i>
<code>trace</code>	<i>Trace or track Python statement execution.</i>
<code>traceback</code>	<i>Print or retrieve a stack traceback.</i>
<code>tracemalloc</code>	<i>Trace memory allocations.</i>
<code>tty</code> <i>(Unix)</i>	<i>Utility functions that perform common terminal control operations.</i>
<code>turtle</code>	<i>An educational framework for simple graphics applications</i>
<code>turtledemo</code>	<i>A viewer for example turtle scripts</i>
<code>types</code>	<i>Names for built-in types.</i>
<code>typing</code>	<i>Support for type hints (see :pep:`484`).</i>

## **u**

<code>unicodedata</code>	<i>Access the Unicode Database.</i>
<code>unittest</code>	<i>Unit testing framework for Python.</i>
<code>unittest.mock</code>	<i>Mock object library.</i>
<code>urllib</code>	
<code>urllib.error</code>	<i>Exception classes raised</i>

<code>urllib.parse</code>	by <code>urllib.request</code> . Parse URLs into or assemble them from components.
<code>urllib.request</code>	Extensible library for opening URLs.
<code>urllib.response</code>	Response classes used by <code>urllib</code> .
<code>urllib.robotparser</code>	Load a <code>robots.txt</code> file and answer questions about fetchability of other URLs.
<code>usercustomize</code>	
<code>uu</code>	<b>Deprecated:</b> Encode and decode files in uuencode format.
<code>uuid</code>	UUID objects (universally unique identifiers) according to RFC 4122

## v

<code>venv</code>	Creation of virtual environments.
-------------------	-----------------------------------

## w

<code>warnings</code>	Issue warning messages and control their disposition.
<code>wave</code>	Provide an interface to the WAV sound format.
<code>weakref</code>	Support for weak references and weak dictionaries.
<code>webbrowser</code>	Easy-to-use controller for web browsers.
<code>winreg</code> (Windows)	Routines and objects for manipulating the Windows registry.
<code>winsound</code> (Windows)	Access to the sound-

	<i>playing machinery for Windows.</i>
<code>wsgiref</code>	<i>WSGI Utilities and Reference Implementation.</i>
<code>wsgiref.handlers</code>	<i>WSGI server/gateway base classes.</i>
<code>wsgiref.headers</code>	<i>WSGI response header tools.</i>
<code>wsgiref.simple_server</code>	<i>A simple WSGI HTTP server.</i>
<code>wsgiref.types</code>	<i>WSGI types for static type checking</i>
<code>wsgiref.util</code>	<i>WSGI environment utilities.</i>
<code>wsgiref.validate</code>	<i>WSGI conformance checker.</i>

## X

<code>xdrlib</code>	<b>Deprecated:</b> <i>Encoders and decoders for the External Data Representation (XDR).</i>
<code>xml</code>	<i>Package containing XML processing modules</i>
<code>xml.dom</code>	<i>Document Object Model API for Python.</i>
<code>xml.dom.minidom</code>	<i>Minimal Document Object Model (DOM) implementation.</i>
<code>xml.dom.pulldom</code>	<i>Support for building partial DOM trees from SAX events.</i>
<code>xml.etree.ElementInclude</code>	<i>Implementation of the</i>
<code>xml.etree.ElementTree</code>	<i>ElementTree API.</i>
<code>xml.parsers.expat</code>	<i>An interface to the Expat non-validating</i>

*XML parser.*

**xml.parsers.expat.errors**

**xml.parsers.expat.model**

**xml.sax** *Package containing  
SAX2 base classes and  
convenience functions.  
Base classes for SAX*

**xml.sax.handler** *event handlers.*

**xml.sax.saxutils** *Convenience functions  
and classes for use with  
SAX.*

**xml.sax.xmlreader** *Interface which SAX-  
compliant XML parsers  
must implement.*

**xmlrpc**

**xmlrpc.client** *XML-RPC client access.*

**xmlrpc.server** *Basic XML-RPC server  
implementations.*

## **z**

**zipapp** *Manage executable  
Python zip archives*

**zipfile** *Read and write ZIP-  
format archive files.*

**zipimport** *Support for importing  
Python modules from  
ZIP archives.*

**zlib** *Low-level interface to  
compression and  
decompression routines  
compatible with gzip.*

**zoneinfo** *IANA time zone support*

# Download Python 3.12.0 Documentation

**Last updated on: Oct 12, 2023.**

To download an archive containing all the documents for this version of Python in one of various formats, follow one of links in this table.

Format	Packed as .zip	Packed as .tar.bz2
PDF (US-Letter paper size)	<a href="#">Download</a> (ca. 13 MiB)	<a href="#">Download</a> (ca. 13 MiB)
PDF (A4 paper size)	<a href="#">Download</a> (ca. 13 MiB)	<a href="#">Download</a> (ca. 13 MiB)
HTML	<a href="#">Download</a> (ca. 9 MiB)	<a href="#">Download</a> (ca. 6 MiB)
Plain Text	<a href="#">Download</a> (ca. 3 MiB)	<a href="#">Download</a> (ca. 2 MiB)
EPUB	<a href="#">Download</a> (ca. 5 MiB)	

These archives contain all the content in the documentation.

## Unpacking

Unix users should download the .tar.bz2 archives; these are bzipipped tar archives and can be handled in the usual way using tar and the bzip2 program. The [InfoZIP](#) unzip program can be used to handle the ZIP archives if desired. The .tar.bz2 archives provide the best compression and fastest download times.

Windows users can use the ZIP archives since those are customary on that platform. These are created on Unix using the InfoZIP zip program.

## Problems

If you have comments or suggestions for the Python documentation, please send email to [docs@python.org](mailto:docs@python.org).

# Python 3.12.0 documentation

Welcome! This is the official documentation for Python 3.12.0.

## Parts of the documentation:

### Installing Python Modules

installing from the "Python Packaging Guide" & other sources

### Distributing Python Modules

publishing modules for installation by others

### Extending and Embedding

helping you write your C/C++ extensions

### Python C Reference

describes Python C API and how to use it

### Python Setup and Usage

frequently asked questions (on platforms!)

### Python HOWTOs

in-depth documents on specific topics

## Indices and tables:

### Search Page

search the docs and find what you need

### Complete Table of Contents

list of all sections, classes, and subsections

### Glossary

the most important terms explained

## Meta information:

### Reporting bugs and giving feedback

[Copyrighting to Docs](#)  
[About the documentation](#)

# Distributing Python Modules

## Note

Information and guidance on distributing Python modules and packages has been moved to the [Python Packaging User Guide](https://packaging.python.org/) [https://packaging.python.org/], and the tutorial on [packaging Python projects](https://packaging.python.org/en/latest/tutorials/packaging-projects/) [https://packaging.python.org/en/latest/tutorials/packaging-projects/].

# Argument Clinic How-To

## Note

The Argument Clinic How-TO has been moved to the [Python Developer's Guide](https://devguide.python.org/development-tools/clinic/) [https://devguide.python.org/development-tools/clinic/].
